## ABSTRACT

### CELLULAR MECHANISMS UNDERLYING MYOGENIC REACTIVITY IN ISOLATED ARTERIOLES

Hui Zou

Eastern Virginia Medical School and Old Dominion University, 1995

Advisor: Dr. Michael A. Hill

The myogenic reactivity provides one of the principal mechanisms for blood flow autoregulation. The aims of the performed studies described in this dissertation were to test the role of  $[Ca^{2+}]_i$  and MLC phosphorylation in arteriolar myogenic reactivity and further examine the source(s) of activator  $Ca^{2+}$  required to initiate and maintain myogenic vasoconstriction. In addition, the possible underlying mechanism of contractile protein expression was also addressed.

These studies used male Sprague Dawley rats of 200~350 grams body weight. Experiments were carried out using rat cremaster first order arterioles and mesenteric vessels. Gel electrophoresis and immunoblotting techniques were employed to analyze and identify the contractile protein isoforms and myosin light chain phosphorylation while the functional aspects of the studies were performed on isolated, cannulated vessel preparations. Intracellular calcium was measured using a video based image system with fura-2 as a fluorescent  $Ca^{2+}$  indicator. A fluorescence image intensity ratio of 340nm over 380nm excitation wavelengths was accepted as a measurement of  $[Ca^{2+}]_i$ . Samples for measuring MLC phosphorylation were collected by quickly freezing the vessels at the desired time points after different treatments according to the

protocols. Gel scanning and result quantification were performed with the aid of a computerized image analysis system.

The following conclusions were drawn from the studies presented in this dissertation:

1) Myogenic reactivity may, in part, relate to differences in structural composition of contractile proteins; 2)  $[Ca^{2+}]_i$  and MLC phosphorylation play obligatory roles in the setting of arteriolar spontaneous tone and myogenic reactivity; 3) Wall tension appears to be the detected variable and a regulatory factor during the arteriolar myogenic reactivity; 4)  $\alpha$ -adrenergic agonist induced-arteriolar contraction also depends on increases in  $[Ca^{2+}]_i$  and MLC phosphorylation, however, signaling pathways appear to differ from that described for myogenic contraction. Further, mechanisms involving the contractile element  $Ca^{2+}$  sensitization also contribute to the agonist-induced response; 5) The extracellular  $Ca^{2+}$  source is most important in the maintenance of arteriolar basal tone and the myogenic contraction. While  $Ca^{2+}$  entry from the extracellular environment, largely via VOCs, is a mandatory process,  $Ca^{2+}$  release from intracellular stores may also be involved in the myogenic constriction. An additional  $Ca^{2+}$  entry mechanism, possibly receptor-operated  $Ca^{2+}$  channels, is involved in the agonist-induced contractions.

## **ACKNOWLEDGMENT**

I would like to express my sincere gratitude to the members of my guidance committee: Dr. Stephen J. Beebe, Dr. Peter F. Blackmore, Dr. Barbara Hargrave, Dr. Paul H. Ratz for their kind help and advice all these four and a half years. My special thanks go to Dr. Michael A. Hill, my major advisor. He led me into the world of microcirculation and started my career in life sciences which is so much fun. He has not only been an exemplary mentor, but also a valued friend. Thank you, Mike.

I would also like to thank my family: my wife Xiaojun, who gave me so much support throughout these years; my son Alex, who always cheers me up; my mom Junxiu Sun and my mother-in-law Shuqing Chen, who have been great help. I could not have made it without you. I owe you a lot.

## CHAPTER I

### BACKGROUND AND INTRODUCTION

Arterioles (approximately 10–100 $\mu$ m in diameter) are the terminal branches of the arterial system. They are also termed resistance vessels because the greatest functional resistance (50–80%) to blood flow resides in this segment of the circulation, and as such, arterioles play a very important role in regulating local blood flow. The wall of resistance vessels consists primarily of smooth muscle cells wrapped circumferentially around the vessel lumen, which is lined by a monolayer of endothelial cells in contact with the blood (Rhodin, 1967). In order to provide a framework for understanding arteriolar vasomotor function, a general background introduction to the myogenic phenomenon and the related mechanisms for smooth muscle contraction are provided in the remainder of the chapter.

#### Blood Flow Regulation and Myogenic Phenomenon

Arterioles characteristically show **basal tone** (also called **spontaneous tone** or **myogenic tone**) - a partially constricted state of smooth muscle cells of the vessel wall from which they can relax or further constrict in response to different stimuli. It is this unique characteristic that enables the arterioles to function as the major site for local blood flow regulation.

Although variation exists between organs, the blood flow to each tissue of the body tends to be tightly controlled in relation to the tissue need. Local blood flow regulation, or

autoregulation, involves several mechanisms including myogenic and metabolic responsiveness (Granger, et al., 1988; Johnson, 1986). Stabilizing tissue oxygen is the proposed ultimate goal for the metabolic mechanism. When tissue oxygenation falls below normal, a signal (possibly through releasing of vasodilator metabolites, e.g. adenosine) is transmitted to the arteriolar smooth muscle cell to elicit relaxation. Consequently, blood flow through microcirculation increases and more oxygen is transported from capillaries thereby returning tissue oxygenation to normal and providing convective washout of accumulated metabolites. According to the **myogenic mechanism**, vascular smooth muscle cells constrict in response to an increase in transmural pressure and relax following a pressure reduction. The increased (decreased) blood flow resulting from the elevation (reduction) of blood pressure is then normalized by the decrease (increase) in vessel cross-section area due to the constriction (relaxation). A relationship between blood flow and vessel cross section area (radius) is shown below:

$$\text{Flow (F)} = k \Delta P r^4 \quad (1-1)$$

here, k is a constant related to blood viscosity and vessel length;  $\Delta P$  is blood pressure change along the vessel; and r is radius of the vessel.

In many tissues of the body, both metabolic and myogenic mechanisms are required for a complete local microcirculatory regulation. It has been considered that the metabolic mechanism dominates when tissue oxygenation is below normal, while myogenic mechanism supersedes when the prevailing tissue oxygen tension is higher than normal (Granger, et al., 1988). It was recently suggested that these mechanisms reside in different arteriolar segments:

metabolic control exerts a dominant effect on the smallest arterioles ( $<20\mu\text{m}$ ) and myogenic control dominates in vessels  $20\text{--}30\mu\text{m}$  (Kuo, et al., 1992).

In addition to blood flow and capillary pressure regulation, the myogenic response may also be critically important for the establishment of basal vascular resistance and may interact additively or negatively with other mechanisms (Kuo, et al., 1991). The control of resistance is very effective because resistance is inversely proportional to the 4th order of vessel radius. Figure 1-1 illustrates arteriolar diameter responses to changes in transmural pressure.

Figure 1-1. Schematic illustration of arteriolar diameter response to intraluminal pressure changes.

Myogenic activity of blood vessels was first theorized by Sir William Maddock Bayliss at the turn of the century (Bayliss, 1902). Two of the phenomena Bayliss observed in his experiments contributed most in leading to this proposition. He found that a brief reduction of perfusion pressure to the hindquarters of the dog caused expansion of the limb beyond its

control volume when the pressure was restored. More directly, he also observed that when the internal pressure of an isolated carotid artery segment was elevated, it began to “writhe like a worm”. However, the support for the myogenic phenomena remained weak and some other researchers suggested alternative explanations such as local accumulation of chemical factors. Until 1950's, most physiologists still regarded the blood vessels as being principally under the central control of vasodilator and vasoconstrictor nerves, with local mechanisms playing a minor role (Johnson, 1980). The studies from Folkow (1949 and 1952) provided another milestone in the study of myogenic reactivity. Using perfused cat hindquarters, he showed that despite a transient increase, flow returned towards its control level after an elevation of the arterial perfusion pressure. A transient flow decrease followed by a gradual increase towards control level was seen with a reduced perfusion pressure. Further, he demonstrated that complete denervation of muscular, cutaneous, and splanchnic vessels did not abolish vascular tone. His study provided sufficient evidence that there could be a myogenic origin for vascular tone and that it again became a matter of serious consideration.

Following Folkow's studies there was a resurgence of interest in the role of the myogenic response in local blood flow regulation. In particular, numerous studies provided descriptive data dealing with the presence or absence of myogenic behavior within specific vascular beds and at specific sites within a vascular network (for review see Johnson, 1980 and 1986). More recently, with the development of methods for studying signal transduction, the focus has shifted to understanding the cellular events which underlie myogenic vasoconstriction. Before describing such studies, a brief overview of smooth muscle

contraction, signal transduction mechanisms related to contraction and the role of specific proteins in contractile function is provided. Following this the current understanding of the cellular mechanisms involved in myogenic reactivity will be presented.

### Smooth Muscle Contraction

The myogenic reactivity has been proved to be smooth muscle originated and is independent of endothelium (see the section of “previous knowledge on myogenic reactivity” in this chapter). Therefore, myogenic reactivity, per se, is smooth muscle contraction. Although the sliding filament contractile mechanism for striated muscles was detailed decades ago, smooth muscle contraction had remained a mystery until the 1980’s. In the late 70’s, studies started to show that myosin light chain (MLC) phosphorylation mediated by myosin light chain kinase (MLCK) is a key event leading to smooth muscle contraction (Cassidy, et al., 1979; Sobieszek, 1977). Evidence supporting this thick-filament regulation hypothesis has, since, been accumulating and the activation of MLCK pathway has been demonstrated to be both necessary and sufficient to trigger contraction of smooth muscle (Driska, et al., 1981; Hai and Murphy, 1988; Itoh, et al., 1989; Murphy, 1982)

### *Myosin Light Chain Phosphorylation and Smooth Muscle Contraction*

Intracellular calcium concentration ( $[Ca^{2+}]_i$ ) is agreed to be the primary determinant of smooth muscle contraction, and it is now generally accepted that intracellular free  $Ca^{2+}$  binding to the protein calmodulin (CaM) forms the initial event in smooth muscle contraction. The regulatory  $Ca^{2+}$ /CaM complex ( $4Ca^{2+}$ -CaM) then binds to the catalytic subunit of MLCK and activates this enzyme. MLCK phosphorylates serine 19 (high concentration MLCK also

phosphorylates threonine 18 *in vitro*) (Ikebe and Hartshorne, 1985) on the 20kD regulatory light chain of myosin which leads to an increase in the actin-activated myosin ATPase. Physiologically, MLC phosphorylation would be associated with attachment and cycling of cross bridges to actin and the subsequent development of force or increase in maximal shortening velocity. A decrease in  $[Ca^{2+}]_i$  inactivates MLCK and dephosphorylation of MLC by a protein phosphatase (Myosin Light Chain Phosphatase, MLCP) would lead to relaxation (Kamm and Stull, 1985; Stull, et al., 1991; Walsh, 1991). A diagram of the molecular events involved in smooth muscle contraction and relaxation is shown in figure 1-2.

### *Latch-bridge Hypothesis*

Although the proposed general scheme of MLC phosphorylation causing smooth muscle contraction is widely applicable and generally accepted, many investigations have shown that the events illustrated in figure 1-2 are not sufficient to describe all the cellular processes involved in smooth muscle contraction. Murphy and his colleagues originally observed a dissociation of force and myosin phosphorylation (Dillon, et al., 1981). Following a high  $K^+$  stimulation of swine carotid artery, they found a correlation between MLC phosphorylation and maximum shortening velocity during force development, however, isometric force was maintained during prolonged stimulation while MLC phosphorylation decreased to about 25% from a peak value of 65%. Similar observations were also reported by other investigators using different (vascular and tracheal smooth muscles) tissues (Aksoy, et al., 1983; Kamm and Stull, 1985). To explain this, Murphy and colleagues (Dillon et al., 1981;

Figure 1-2. Myosin phosphorylation-dephosphorylation as the primary mechanism in the regulation of smooth muscle contraction. CaM, calmodulin; MLCK, myosin light chain kinase; MLCP, myosin light chain phosphatase.

Hai and Murphy, 1988) put forward a ‘Latch-bridge Hypothesis’ which suggests a state of dephosphorylated myosin attaching to actin during the prolonged smooth muscle activation, forming a noncycling cross-bridge (the latch-bridge). This latch-bridge mechanism appears to function only after the initial activation and  $\text{Ca}^{2+}$  transient that lead to myosin phosphorylation and stress development (Chatterjee and Murphy, 1983). Figure 1-3 shows a schematic diagram of this proposed mechanism.

Figure 1-3. Latch-bridge model

While the physiologically based ‘latch-bridge’ model explains many observations relating MLC phosphorylation and force development or maximal shortening velocity, to date, there have been no biochemical studies that directly demonstrate this unique form of myosin cross bridge.

#### *Protein Kinase C Activation and Smooth Muscle Contraction*

An alternative explanation to this dissociation of force from MLC phosphorylation has been proposed by Rasmussen, et al. (1987). These investigators defined a two domain model

for smooth muscle cells: caldesmon - tropomyosin - actin - myosin (CD-TM-A-M) domains and filamin - Actin - desmin (F-A-D) domains. According to this model, the latch mechanism is not caused by the formation of a specific latch bridge between actin and myosin, but to a reorganization and stabilization of the supramolecular organization of the components of the F-A-D domain. Briefly, in the early phase of contraction, the activation of MLCK by  $\text{Ca}^{2+}/\text{CaM}$  causes MLC phosphorylation which leads to the formation of cycling cross-bridges of actin and myosin and thus development of tension. During tension development, the F-A-D fibrillar domain undergoes a re-organization. In addition, the activation of protein kinase C (PKC) leads to the phosphorylation of desmin, synemin, caldesmon and several cytosolic proteins. While the MLC phosphorylation is transient and soon falls towards near basal value, tension is maintained as a consequence of the stabilization of the F-A-D domain by the late-phase phosphorylation.

Since then, involvement of PKC in smooth muscle contraction has attracted much attention. Both  $\text{Ca}^{2+}$ -dependent ( $\alpha$ ,  $\beta$ ) and  $\text{Ca}^{2+}$ -independent PKC isoforms ( $\epsilon$ ,  $\zeta$ ) have been found in smooth muscle cells and both classes have been implicated in the modulation of smooth muscle contraction (Andrea and Walsh, 1992; Lee and Severson, 1994). Although biochemical studies have demonstrated that PKC directly phosphorylates MLC at serine 1, serine 2 and threonine 9 (Bengur, et al., 1987; Ikebe, et al., 1987), such phosphorylation alone has no effect on the enzymatic properties of myosin. On the other hand, PKC-catalyzed phosphorylation reduces by approximately 50% the actin-activated ATPase activity of myosin previously phosphorylated at serine 19 by MLCK (Nishikawa, et al., 1983). However, it is

interesting to notice that phorbol 12,13-dibutyrate (PDB, an exogenous PKC activator) or  $\alpha$ -agonists such as phenylephrine, which generates an endogenous PKC activator 1,2-diacylglycerol (DAG), does not cause phosphorylation at any of the PKC sites in myosin, but only at serine 19 with some phosphorylation at threonine 18 (Singer, et al., 1989). MLCK is, therefore, the primary enzyme that catalyzes the MLC phosphorylation. PKC can also phosphorylate MLCK, but, there is evidence to suggest that the phosphorylation of MLCK by PKC does not affect contractility (Stull, et al., 1990). It seems that contractions elicited by agonists that trigger phosphoinositide turnover and generation of DAG do not involve PKC-catalyzed phosphorylation of either MLC or MLCK. For example, Kitazawa et al. found (1991) found that in  $\alpha$ -toxin skinned vessel, GTP $\gamma$ S, which mimics the agonist-induced G-protein activation, did not further increase MLC phosphorylation hence had no effect on MLCK activity. And this idea is also supported by the study from Rembold and Murphy (1988). They examined the  $[Ca^{2+}]_i$  and MLC phosphorylation following a PDB stimulation in hog carotid artery and found that PDB can cause an increase in  $[Ca^{2+}]_i$ , and the subsequent increase in MLC phosphorylation, due to the elevated  $[Ca^{2+}]_i$ , quantitatively explains the contraction. Although other proteins such as putative thin-filament regulatory proteins, caldesmon and calponin, can also be phosphorylated by PKC *in vitro*, substrates of PKC under physiological conditions are yet to be identified to specify the role of PKC in smooth muscle contraction.

*Thin-filament Regulation of Smooth Muscle Contraction*

Inspired by the idea of PKC involvement, recent research from several other groups proposed another mechanism regulating contractile protein activation - thin filament regulation (Abe, et al., 1990; Marston and Redwood, 1992; Sobue and Sellers, 1991; Winder and Walsh, 1990). Caldesmon and calponin may play important roles in smooth muscle contraction according to this hypothesis. Caldesmon is a major calmodulin- and actin-binding protein found in smooth muscle and other cells (Haeberle et al., 1992; Mabuchi, et al., 1992; Lehman, et al., 1990). *In vitro* studies have demonstrated that caldesmon inhibits superprecipitation and actin-activated myosin  $Mg^{2+}$ -ATPase activity (Nagi and Walsh, 1984; Sobue, et al., 1982; Marston and Lehman, 1985) suggesting that caldesmon inhibits actomyosin interaction. There is also evidence to show that caldesmon regulates smooth muscle contraction by providing a basal resting inhibition of vascular tone and that exogenously added caldesmon relaxes permeabilized smooth muscle fiber preparations (Katsuyama, et al., 1992; Taggart and Marston, 1988). Studies from Chalovich and colleagues (1993) suggested that caldesmon increases the level of MLC phosphorylation required for smooth muscle activation in skinned gizzard muscle fibers. But, these authors further pointed out that caldesmon does not act to maintain force in smooth muscle by cross-linking myosin with actin since competition of binding of caldesmon with myosin does not cause a reduction in tension. Phosphorylation of caldesmon *in vitro* by PKC reversed its inhibition on actomyosin ATPase. However, comparison of the phosphopeptide maps of caldesmon phosphorylation, from *in vitro* phosphorylation by PKC with that by phorbol ester stimulation in intact smooth muscle, suggested that the putative cellular

caldesmon kinase is not PKC (Lee and Severson, 1994). It has been suggested that caldesmon from intact vascular smooth muscle was phosphorylated by mitogen-activated protein (MAP) kinase (Adam and Hathaway, 1993). Further, a recent study from Katoch and Moreland (1995) suggested that in swine carotid artery, MAP kinase is activated in response to all forms of contractile stimulation, and the activated MAP kinase phosphorylates caldesmon and releases the inhibition of caldesmon on actomyosin interaction. This disinhibition allows an inherent level of myosin ATPase activity to be expressed. However, there is also evidence against this disinhibition by the phosphorylation of caldesmon. Pinter and Marston (1992) found that *in vitro* phosphorylation of vascular smooth muscle caldesmon by endogenous kinase did not change its inhibitory effects on actin-tropomyosin activated myosin  $Mg^{2+}$ -ATPase. Incorporation of caldesmon into native or synthetic thin filament did not alter its phosphorylation by the crude mixture containing endogenous "caldesmon kinase" hence indicating a more "*in vivo*" situation in their study. A recent report from Nixon et al. (1995) demonstrated that phosphorylation of caldesmon by MAP kinase has no effect on  $Ca^{2+}$  sensitivity in rabbit smooth muscle. Due to the controversial evidence for the functions of caldesmon, further studies are needed to clarify the role of caldesmon in regulating smooth muscle contraction.

Calponin is a smooth muscle specific, 34 kD calmodulin-binding troponin T-like protein. Structural studies demonstrated that intracellular calponin is colocalized on thin filament and share an identical distribution to that of actin and tropomyosin (Takahashi, et al, 1986; Walsh, et al., 1993). It has been shown *in vitro* that calponin binds to actin and

tropomyosin in a  $\text{Ca}^{2+}$ -independent manner and bind to calmodulin  $\text{Ca}^{2+}$ -dependently.

Calponin inhibits the actomyosin ATPase and can be phosphorylated by PKC and  $\text{Ca}^{2+}$ /CaM-dependent protein kinase II (CaM kinase II) and dephosphorylated by a type 2A phosphatase (Winder, et al., 1992). Upon phosphorylation, the inhibitory effect of calponin is completely reversed while the dephosphorylation of calponin completely restores the ability of calponin to inhibit the actomyosin ATPase. Calponin phosphorylation also occurs in intact toad stomach smooth muscle strips which supports the hypothesis that calponin may be regulated *in vivo* by phosphorylation-dephosphorylation (Winder, et al., 1993).

### *Signal Transductions Involved in Agonist Induced Smooth Muscle Contractions*

An agonist-induced smooth muscle contraction is initiated by the binding of agonists to their receptors on the plasma membrane. A simplified illustration diagram is shown in figure 1-4 where norepinephrine (NE), a neurotransmitter released from periarteriolar neurons, is used as an example in the diagram. Upon binding to the  $\alpha_1$  receptor (on smooth muscle cell membrane), NE activates a membrane bound (more exactly, membrane receptor bound) trimeric GTP-binding and hydrolyzing protein (G-protein). An activated G-protein binds to GTP and the hydrolysis of GTP to GDP causes inactivation of the protein. The activated G-protein ( $G_q$ ), in turn, leads to the activation of phospholipase  $C_p$  (PLC) on cell membrane which catalyzes the hydrolysis of phosphatidylinositol 4,5-bisphosphate ( $\text{PIP}_2$ ), a plasma membrane lipid. Although it has been considered that the  $\alpha$ -subunit of  $G_q$  is responsible for PLC activation, the  $\beta\gamma$ -dimer is also suggested play a role in the signaling (Clapham and Neer, 1993). Two important cellular messengers are generated as the products of this hydrolysis:

Figure 1-4 Smooth muscle cellular events following the binding of NE to its receptor. DAG, 1,2-diacylglycerol; NE, norepinephrine; IP<sub>3</sub>, inositol 1,4,5-*tris*phosphate; PIP<sub>2</sub>, phosphatidylinositol 4,5-*bis*phosphate; PKC, protein kinase C; PLC<sub>β</sub>, phospholipase C<sub>β</sub>; R, receptor; ROC, receptor operated channel; VOC, voltage operated channel.

1,4,5-*triphosphate* ( $\text{IP}_3$ ) and DAG. While DAG is an endogenous PKC activator,  $\text{IP}_3$  can bind to its receptors on the membrane of sarcoplasmic reticulum (SR) and release  $\text{Ca}^{2+}$  from intracellular stores (Birnbaumer and Brown, 1990). NE, in addition to its reported capability of increasing  $\text{Ca}^{2+}$  entry through putative receptor operated  $\text{Ca}^{2+}$  channels (ROC) without significant changes in membrane potential, can also depolarize arterial smooth muscles and, therefore, increase the opening of voltage-operated-channels (VOC) (for review, see Nelson, et al., 1990). The increase in  $[\text{Ca}^{2+}]_i$  will activate MLCK and lead to the contraction of smooth muscle. An increase in PKC activity following an agonist stimulation (due to the generation of DAG) is considered to have a regulatory effect on smooth muscle contraction (e.g. sensitizing the contractile apparatus).

#### *Regulation of $\text{Ca}^{2+}$ -Sensitivity*

Studies revealed that the force/ $\text{Ca}^{2+}$  ratio is generally higher during smooth muscle activation by agonists than by a depolarization induced increase in  $[\text{Ca}^{2+}]_i$  (Nishimura, et al., 1990), indicating a  $\text{Ca}^{2+}$  sensitizing effect of agonists. Furthermore, it has also been demonstrated that agonist-induced force generation can occur in the absence of increase in  $[\text{Ca}^{2+}]_i$  in vascular smooth muscle preparations (Eiichi, et al., 1991; Moreland, et al., 1992). A decrease in  $\text{Ca}^{2+}$ -sensitivity was also reported in studies showing force can decline while  $[\text{Ca}^{2+}]_i$  is maintained (Himpens, et al., 1989; Somlyo, 1989).

Traditionally, it has been considered that MLCK is the only enzyme that is regulated during the MLC phosphorylation while MLCP activity, in particular, remains constant. However, recent findings suggest that the protein phosphatase that dephosphorylates Serine 19

of MLC can also be regulated (inhibited) . It appears that the inhibition of this phosphatase, possibly by PKC, is the main mechanism of G-protein coupled  $\text{Ca}^{2+}$ -sensitization (Collins, et al., 1992; Itoh, et al., 1993; Katsuyama and Morgan, 1993; Kitazawa, et al., 1991). Inhibition of the phosphatase increases MLC phosphorylation and hence the force at given  $[\text{Ca}^{2+}]_i$ . Recently, arachidonic acid (AA) has also been implicated as a potential cellular messenger that mediates signaling from membrane receptors to the myosin bound phosphatase (Gong, et al, 1992; Somlyo and Somlyo, 1994).

Although the conventional heterotrimeric G-protein is considered to play a primary role in  $\text{Ca}^{2+}$ -sensitization, the possibility for the contribution of monomeric G-protein family has not been ruled out. Satoh et al. (1993) recently reported that H-ras p21 proteins increase  $\text{Ca}^{2+}$ -responsiveness of smooth muscle contraction in  $\beta$ -escin skinned guinea pig small mesenteric arteries, suggesting involvement of tyrosine kinase pathway in vascular smooth muscle contraction.

Phosphorylation of MLCK at a specific serine residue in the CaM-binding domain (site A) by several kinases reduces its affinity for CaM and consequently its kinase activity (Stull, 1991). Phosphorylation of MLCK by one of these kinases, CaM kinase II, occurs in vivo and is suggested as a physiological mechanism for  $\text{Ca}^{2+}$ -desensitization. But, it requires a higher  $[\text{Ca}^{2+}]_i$  than activation of MLCK does due to the lower affinity of CaM kinase for  $\text{Ca}^{2+}$ /CaM than that of MLCK.

### Intracellular Calcium

The  $[Ca^{2+}]_i$  is precisely regulated and is maintained at a level of about 100nM under resting conditions, despite extracellular  $[Ca^{2+}]$  and the SR  $[Ca^{2+}]$  in the mM range. Upon activation,  $[Ca^{2+}]_i$  can increase dramatically to 500-700 nM (Williams and Fay, 1986). This increased  $Ca^{2+}$  comes from either the extracellular pool via various  $Ca^{2+}$  channels in the plasma membrane or the intracellular pools (presumably SR) via different release mechanisms. The removal of  $Ca^{2+}$  from cytosol is accomplished by extrusion via  $Na^+-Ca^{2+}$  exchangers and  $Ca^{2+}$ -ATPase pumps in sarcolemma or uptake into intracellular stores by  $Ca^{2+}$ -ATPase on SR membrane. To help understanding the  $Ca^{2+}$  homeostasis, especially those studies discussed in chapter 6, the  $[Ca^{2+}]_i$  adjustment mechanisms that may be involved in smooth muscle contraction are briefly described below.

#### *Voltage Operated $Ca^{2+}$ Channels*

The VOCs are channels that are gated by the membrane potential: opening at more positive potentials (depolarized states) and closing at more negative potentials (hyperpolarized states). The thresholds for VOC opening are different among different channel types. The arterial smooth muscle cells, *in vivo*, have stable resting membrane potentials between -60 and -75mV (Nelson, et al., 1990). More positive potentials (depolarization) can open the VOC and cause an influx of  $Ca^{2+}$  to increase  $[Ca^{2+}]_i$ . Several types of  $Ca^{2+}$  VOCs have been found: Long-lasting, large capacitance (L-) type, transient (T-) type, P-type, Q-type, and neuron specific (N-) type. Studies on P-, Q- and N-type VOCs have been mostly limited to neuronal cells. Although T-type channels are also reported to be present in some, but not all, smooth muscle

cells (Benham, et al., 1987; Nelson and Worley, 1989), L-type channels are the ones that have been extensively studied because the maintained arterial tone depends strongly on this channel and transient  $\text{Ca}^{2+}$  influxes are likely to play a minimal role in the steady state (Nelson, et al., 1990). The activity of the L-type VOCs can be modulated by different agonists (e.g. Bay K8644) and antagonists (e.g. nifedipine). Cell depolarization using high  $\text{K}^+$  solution is the most commonly used pharmacological method for VOC study. Although  $\text{Ca}^{2+}$  release from intracellular stores is considered to contribute most of the  $[\text{Ca}^{2+}]_i$  rise following an agonist stimulation, opening of VOCs by depolarizing cell membrane has also been observed (for review, see Nelson, et al., 1990). Three classes of L-type  $\text{Ca}^{2+}$  VOC blockers have been developed: the phenylalkylamines (e.g., verapamil), the dihydropyridines (e.g., nifedipine) and the benzothiazepines (e.g., diltiazem).

#### *Receptor Operated $\text{Ca}^{2+}$ Channels*

ROCs have been suggested to exist in many cell types (Felder, et al., 1992; Llopis, et al., 1992; Osage, et al., 1989). By definition, binding of agonist to the receptor directly operates the opening and closing of the channel. These channels are proposed to be distinct from VOCs and their activities are independent of membrane potential. However, the presence of smooth muscle ROCs remains more putative and controversial. It seems that for each of the reasons indicating the presence of ROC in smooth muscle cells there is an alternative explanation (Nelson, et al., 1990). Also, the studies have been limited to the contractility studies and  $^{45}\text{Ca}^{2+}$ -influx experiments using intact tissues or the studies of  $\text{Ca}^{2+}$  current across membrane patches (Kwan, 1991). There are studies showed that a group of ginsenosides block

ROCs, and these drugs may represent a class of novel ROC antagonists (Guan, et al., 1988; and Kwan, et al., 1990).

### *Stretch Activated $\text{Ca}^{2+}$ Channels*

Since its discovery in cultured skeletal muscle cells in 1984 (Guharay and Sachs), mechanosensitive ion channels or stretch activated  $\text{Ca}^{2+}$  channels (SACs) have been identified in a variety of cell types. The opening of these channels depends on the stretching of the cell membrane. Such channels have also been demonstrated in both visceral (Kirber, et al., 1988) and vascular (Davis, et al., 1992) smooth muscle cells. The vascular smooth muscle SACs are not cation selective and their relative selectivities for cations are suggested as follows:  $\text{K}^+ > \text{Na}^+ > \text{Ba}^{2+} > \text{Ca}^{2+}$  (Davis, et al., 1992). Their conductance for  $\text{Ca}^{2+}$  is apparently low at physiological  $\text{Ca}^{2+}$  concentration so that the  $\text{Ca}^{2+}$  entry through SACs may not be adequate to elicit a substantial contraction. However, due to the very high membrane impedance at rest ( $>1\sim2\text{G}\Omega$ ), inward currents carried by  $\text{Na}^+$  and  $\text{Ca}^{2+}$  through SACs ( $\sim 2.0\text{pA}$ ) could depolarize the cell sufficiently to open  $\text{Ca}^{2+}$  VOCs and lead to a contraction (Davis, et al., 1992; Benham, et al., 1987; and Matsuda, et al., 1991). An ion-selective SAC was reported to be found in rabbit mesenteric arterial smooth muscle cells which appears to be large conductance  $\text{Ca}^{2+}$  activated  $\text{K}^+$  channels (Kirber, et al., 1992). Gadolinium ( $\text{Gd}^{3+}$ ), a non-specific  $\text{Ca}^{2+}$  channel blocking trivalent cation, has been reported to block the SACs (Yang and Sachs, 1989).

### *Intracellular $\text{Ca}^{2+}$ Release via Inositol 1,4,5-trisphosphate Sensitive Channels*

$\text{IP}_3$ , a cellular messenger generated upon receptor activation, causes release of  $\text{Ca}^{2+}$  from intracellular stores in many cells, including smooth muscle. It is generally accepted that

both IP<sub>3</sub> and DAG are formed by the hydrolysis of an inositol lipid precursor stored in the plasma membrane - PIP<sub>2</sub>. Although PLC is the identified enzyme catalyzing the reaction, two major distinct signaling pathways have been suggested: one initiated by a family of G-protein linked receptors and the other by receptors associated with tyrosine kinases (Berridge, 1993). Different PLC isoforms, respectively PLC<sub>β</sub> and PLC<sub>γ</sub>, are involved in these separate receptor mechanisms, and PLC<sub>β1</sub> is the isoform most likely to be responsible for PIP<sub>2</sub> hydrolysis in vascular smooth muscle in response to α<sub>1</sub>-agonists (Lee and Severson, 1994). Meyer et al. (1990) proposed that IP<sub>3</sub> induced Ca<sup>2+</sup> release depends on IP<sub>3</sub> binding sequentially to the its receptors on intracellular store. The kinetics of this release was examined *in vitro* using synaptosomes (Finch et al., 1990), according to his study the response is extremely fast, reaching a maximum within 140ms of adding IP<sub>3</sub>. This finding is in agreement with that the transient increase in [Ca<sup>2+</sup>]<sub>i</sub> following agonist stimulation is due to the Ca<sup>2+</sup> release from intracellular stores. Heparin, which has been reported to be an antagonist to the IP<sub>3</sub> receptor in smooth muscle cells (Chadwick, et al., 1990), can be used as a tool to examine the role of Ca<sup>2+</sup> release in agonist-induced responses.

#### *Intracellular Ca<sup>2+</sup> Release via Ryanodine Sensitive Channels and Calcium Induced Calcium Release*

Ryanodine sensitive channels represent another principal intracellular Ca<sup>2+</sup> channel responsible for mobilizing stored Ca<sup>2+</sup> and as such may contribute to vascular smooth muscle contraction. Although the functions of ryanodine were not apparent until a few years ago, this plant alkaloid has been extensively studied due to its capability in releasing Ca<sup>2+</sup> from

intracellular stores. Three different ryanodine receptor genes have been identified in mammals and are designated as the skeletal, cardiac and brain ryanodine receptor genes or *ryr-1*, *ryr-2* and *ryr-3*, respectively (McPherson and Campbel, 1993). While caffeine is another commonly used ryanodine receptor agonist, it also inhibits cyclic nucleotide phosphodiesterase which causes increases in cytosolic cAMP and cGMP and consequently leads to smooth muscle relaxation by lowering  $[Ca^{2+}]_i$ .

It is well known that calcium-induced calcium release (CICR), an influx of  $Ca^{2+}$  through the sarcolemma triggering the release of additional  $Ca^{2+}$  from SR, plays a very important role in cardiac muscle contraction. Recent studies from cultured smooth muscle cell line as well as skinned taenia caeci preparations indicated that this mechanism may also exist in smooth muscle (Blatter and Wier, 1992; Iino, 1989; Iino, 1990). Further, the CICR channels from smooth muscle cells show properties similar to those observed for skeletal and cardiac CICR channels: it can be activated by  $Ca^{2+}$ , ATP and caffeine and inhibited by  $Mg^{2+}$  (Himpens, et al., 1995). The channel can be locked in an open state by the plant alkaloid ryanodine.

#### *$Ca^{2+}$ -ATPase Pumps*

$Ca^{2+}$ -ATPase pumps belong to a class of transmembrane proteins that transduce the energy liberated by ATP hydrolysis into the transport of ions against a steep electrochemical gradient. While catalyzing this transport the enzyme cycles through two major conformations: one with high  $Ca^{2+}$  affinity and the other with low  $Ca^{2+}$  affinity.  $Ca^{2+}$ -ATPase Pumps are present in plasma membrane as well as in the membrane of intracellular stores, presumably the

SR or a subcompartment of it. They work in concert to maintain a low  $[Ca^{2+}]_i$  and to bring  $[Ca^{2+}]_i$  back to resting levels when stimuli are removed.

Two distinct families of  $Ca^{2+}$ -ATPase pumps have been found to exist in smooth muscle cells. These two types of pumps are encoded by multiple genes and their regulation for activation are also different (Raeymaekers and Wuytack, 1993). The plasma membrane  $Ca^{2+}$ -ATPase pump has a molecular weight of 130kD and is stimulated by CaM, while the SR  $Ca^{2+}$ -ATPase pump does not require CaM for activation and has a molecular weight of 105kD.

Phospholamban is a SR  $Ca^{2+}$ -ATPase regulatory protein. Although the phosphorylation of this protein has been associated with an increased SR  $Ca^{2+}$ -ATPase activity in cardiac muscle, its role in smooth muscle is not clear, because many other SR proteins are also phosphorylated (Raeymaekers and Jones, 1986). Recent insight into the role of cAMP- and cGMP-dependent protein kinases in smooth muscle relaxation has indicated that phospholamban could mediate some of their effects on smooth muscle relaxation. For example, Lincoln and Cornwell (1991, 1993) suggested that elevation of cAMP in smooth muscle lead to activation of both cAMP kinase and cGMP kinase, and activation of the latter leads to a reduction in  $[Ca^{2+}]_i$ . This  $[Ca^{2+}]_i$  reduction may result from phospholamban phosphorylation, enhancing SR  $Ca^{2+}$ -ATPase activity, and from  $IP_3$  receptor phosphorylation, inhibiting  $Ca^{2+}$  release.

Thapsigargin, a tumor promoter first found to transiently increase  $[Ca^{2+}]_i$  without generating  $IP_3$  in neuronal cells (Thastrup, et al., 1990), is identified to be a microsomal  $Ca^{2+}$ -ATPase inhibitor. It blocks the  $Ca^{2+}$  uptake by  $Ca^{2+}$ -ATPase and subsequently

empties intracellular  $\text{Ca}^{2+}$  stores. Cyclopiazonic acid (CPA), an indole tetramic acid metabolite of *Aspergillus* and *Penicillium*, has also been shown to be a highly selective inhibitor of the  $\text{Ca}^{2+}$ -ATPase (Low, et al., 1992; Omote and Mizusawa, 1994). With the aid of these useful pharmacological agents, various studies on  $\text{Ca}^{2+}$  signaling can be performed by functionally removing intracellular  $\text{Ca}^{2+}$  stores.

### *$\text{Na}^+$ - $\text{Ca}^{2+}$ Exchangers*

Sodium-Calcium ( $\text{Na}^+$ - $\text{Ca}^{2+}$ ) exchanger is a countertransport system that translocates  $\text{Na}^+$  and  $\text{Ca}^{2+}$  across the plasma membrane. Under physiological conditions, with the driving force being electrochemical gradient of  $\text{Na}^+$  across the membrane ( $[\text{Na}^+]_i = 10\text{mM}$ ,  $[\text{Na}^+]_o = 140\text{mM}$ ), it allows three  $\text{Na}^+$  to enter the cell in exchange for one  $\text{Ca}^{2+}$ . This exchange system can also transport ions in opposite directions by manipulating the extracellular  $\text{Na}^+$  concentrations during experiments. The activity of the  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchanger has been reported to be regulated by ions (for review, see Matlib 1991; O'Donnell and Owen, 1994). For example, inhibition of  $\text{Na}^+$ - $\text{K}^+$  pump, which increases the intracellular  $\text{Na}^+$  concentration, will promote  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchange. However, there is no evidence to suggest a second messenger-dependent direct modification of the system. It has been hypothesized that a physiological role of  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchanger in vascular smooth muscle is reducing the amplitude and duration of  $\text{Ca}^{2+}$  signals induced by  $\text{Ca}^{2+}$  mobilizing hormones. For example, at a  $[\text{Ca}^{2+}]_i$  of 400nM, the  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchanger is responsible for nearly half of the rate of  $\text{Ca}^{2+}$  removal from the cell, while the  $\text{Ca}^{2+}$ -ATPase is presumably responsible for the removal of the remaining  $\text{Ca}^{2+}$  at that concentration (Fay, et al., 1992).

Further, it was suggested that the  $\text{Na}^+\text{-Ca}^{2+}$  exchanger function is more important for long-term homeostasis of intracellular  $\text{Ca}^{2+}$  (O'Donnell and Owen, 1994).

*Capacitative Calcium Entry and Superficial Buffer Barrier Hypothesis*

A model for receptor-regulated  $\text{Ca}^{2+}$  entry, capacitative calcium entry, is proposed by Putney in 1986 and revised in 1990 (Putney, 1990). According to his model,  $\text{Ca}^{2+}$  content of an agonist- and  $\text{IP}_3$ -regulated intracellular pool regulates the permeability of the plasma membrane to  $\text{Ca}^{2+}$ . The essence of the hypothesis is that the depletion of an intracellular  $\text{Ca}^{2+}$  store by  $\text{IP}_3$  somehow triggers the opening of a pathway for its replenishment from extracellular space. As long as  $\text{IP}_3$  was present, the store would remain empty and  $\text{Ca}^{2+}$  entry across the plasma membrane, into the store and subsequently into the cytoplasm would continue. A postulation follows this model would be that the depletion of the intracellular store by any means will activate the same  $\text{Ca}^{2+}$  entry mechanism. Putney's model explains the observed phenomenon that, in non-excitabile cells as well as in smooth muscle cells, agonist-induced  $\text{Ca}^{2+}$  mobilization was a response of transient release from intracellular stores followed by sustained activation of  $\text{Ca}^{2+}$  entry across plasma membrane (Bohr, 1973; Putney, 1978; Stolze and Schulz, 1980). This proposition was also supported by the study from Takemura, et al. (1989) using thapsigargin. They found, in parotid acinar cells, that this intracellular store  $\text{Ca}^{2+}$ -ATPase inhibitor caused a sustained increase in  $[\text{Ca}^{2+}]_i$  in presence of extracellular  $\text{Ca}^{2+}$  and the addition of methacholine, an agonist that has been proved to release intracellular  $\text{Ca}^{2+}$  and

increase  $\text{Ca}^{2+}$  influx (Takemura and Putney, 1989), failed to further increase the  $\text{Ca}^{2+}$  entry.<sup>25</sup>

Although this model proposed a possible mechanism for the initiation of  $\text{Ca}^{2+}$  entry, it does not provide a strong enough argument regarding the pathway(s) for  $\text{Ca}^{2+}$  to enter the intracellular store from the extracellular space. Together with other findings the observations that  $\text{Ca}^{2+}$  entry is usually associated with an increase in  $[\text{Ca}^{2+}]_i$  (Takemura and Putney, 1989) and existence of an efficient refilling system from cytosol (Kwan, et al., 1990) led to a skepticism regarding the concept of continuous direct filling of the store as initially proposed in the model. Recently, a soluble mediator ( $\text{Ca}^{2+}$  influx factor, CIF), which is released from intracellular organelles upon  $\text{Ca}^{2+}$  depletion, is found in a lymphocyte cell line (Randriamampita and Tsien, 1993). This messenger can cause  $\text{Ca}^{2+}$  influx when applied to several other cells and is presumably responsible for mediating the signal from intracellular  $\text{Ca}^{2+}$  stores to plasma membrane. The discovery of this novel cell messenger gave further support to  $\text{Ca}^{2+}$  capacitative entry hypothesis.

Based on studies of smooth muscle cells, van Breemen and Saida (1989) proposed another model for regulating  $\text{Ca}^{2+}$  entry - the superficial buffer barrier hypothesis. According to this model, peripheral or superficial SR, in addition to  $\text{Ca}^{2+}$  uptake and discharge during smooth muscle relaxation and contraction respectively, also functions as a superficial buffer barrier to  $\text{Ca}^{2+}$  entry from extracellular space into the cytoplasm: a) the superficial SR removes  $\text{Ca}^{2+}$  entering through sarcolemma before it can activate myofilaments; b) the state of the SR with respect to its permeability to  $\text{Ca}^{2+}$  and its rate of

$\text{Ca}^{2+}$ -ATPase activity partly determines the steady state cellular  $\text{Ca}^{2+}$  concentration; and  
 c) a variable  $\text{Ca}^{2+}$  gradient exists near the inner plasmalemmal surface, with  $\text{Ca}^{2+}$  activity increasing nearer that surface. The model was supported by and partially based on ultrastructural studies showing that a portion of the SR is located close to the inner surface of the sarcolemma to which it occasionally joins with via special junctions and the lumen of all SR network is probably contiguous (Somlyo and Franzini-Armstrong, 1985). Although the SR membrane comes close to sarcolemma, there is no evidence for any continuity between the extracellular space and the SR lumen.

According to this model, the superficial buffer barrier is likely to be an important mechanism for increasing the informational content of the  $\text{Ca}^{2+}$  signal in smooth muscle. In addition, it may be a safety factor in protecting small cells having a high surface:volume ratio against the relatively large unregulated  $\text{Ca}^{2+}$  leak (van Breemen et al., 1995).

#### Contractile Protein Isoforms and Their effects on Smooth Muscle Function

Actin, myosin and tropomyosin are usually considered the major contractile proteins and play the primary role in muscle contraction. While the same contractile proteins are found in striated and smooth muscles in general, different isoforms have been identified in different muscle types or within the same muscle type from different tissues. A number of studies have suggested that differences in muscle function reside, to a great extent, in the contractile protein isoform compositions (Aikawa, et al., 1993; Borriene, et al., 1989; Murphy, 1992; Murphy, et al., 1974; Owens, et al., 1986; Somlyo, 1993). Basic knowledge regarding actin, myosin and

tropomyosin isoforms is given below to provide background information for the studies described in Chapter 3.

**Actin** is a cytoskeletal protein that constitutes the major part of the thin filament. Under low ionic conditions, purified actin exists as a single polypeptide chain of 42kD. This monomer is designated as G-actin because of its globular shape. In intact muscle, or under physiological conditions, G-actin polymerizes and form filamentous actin (F-actin). High-resolution electron microscopic studies reveal F-actin as two braid  $\alpha$ -helical strands of globular actin monomers. Actin is such an extraordinarily highly conserved molecule that over 90% homology exists amongst the different isoforms and the difference between the four muscle-specific forms are only a few amino acids concentrated in the N-terminal end of the protein (Vandekerckhove and Weber, 1978). At least six actin isoforms have been found:  $\alpha$ -skeletal,  $\alpha$ -cardiac,  $\alpha$ -smooth muscle (SM),  $\gamma$ -SM,  $\beta$ -nonmuscle (NM), and  $\gamma$ -NM, and the latter four isoforms are all found in smooth muscle cells. These actin isoforms are encoded by different genes (Chang, et al., 1984).

Studies on cellular contractile protein content have been performed among different porcine smooth muscle cells (Cohen and Murphy, 1978). While cellular myosin contents were found to be similar in each tissue (both arterial and nonarterial) tested, the contents of actin, tropomyosin and the calculated weight ratio of average actin:myosin in arterial tissues are significantly higher. In terms of actin and tropomyosin content, smooth muscles have been grouped into arterial smooth muscle and nonarterial smooth muscle (Murphy, 1992). Arterial smooth muscle appears to have about 30% more actin than the other type and this extra is the

$\alpha$ -SM isoform (Cohen and Murphy, 1978; Fatigati and Murphy, 1984). However, no functional significance has been established regarding this finding. Fatigati and Murphy (1984) also showed that muscles that are normally relaxed (visceral tissues) primarily express  $\gamma$ -actin (presumably  $\gamma$ -SM) while muscles that are normally contracted contain greater amounts of  $\alpha$ -SM actin. They also found that in cultured smooth muscle cells,  $\alpha$ -SM actin content decreases with time while  $\beta$ -NM actin and  $\gamma$ -SM and NM isoforms increase. An increase in NM-actin isoform expression characterized the cell with a proliferative, synthetic and secretory phenotype while SM-isoforms are primarily expressed in non-dividing, contractile cells *in vivo*.

**Myosin** is the primary protein of the thick filament in smooth muscle and is a hexamer of two heavy chains and two sets of two light chains. Two smooth muscle myosin heavy chain (MHC) isoforms were identified by Rovner, Thompson and Murphy (1986) according to their migration rate in sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis (PAGE). SM1 and SM2 were assigned to the heavier isoform (~204kD) and the faster migrating isoform (~200kD), respectively. Studies from Babij and Periasamy (1989) demonstrated that the isoform diversity is produced by alternative splicing of the same smooth muscle MHC gene which results in a 43 amino acid difference at the carboxyl terminal. This result gave support to the earlier finding by Eddinger and Murphy (1988) that the two smooth muscle MHCs differ in their light meromyosin. The SM1/SM2 ratios vary in different smooth muscles and appears to be a characteristic for smooth muscle tissues, i.e. it is reasonably constant for a particular tissue (Boels, et al., 1991; Mohammad and Sparrow, 1988; Rovner, Murphy and Owens, 1986). Smooth muscle MHCs can form either homodimers or heterodimers (Kelley, et al., 1992; Tsao

and Eddinger, 1993). Non-muscle (NM) type MHCs are also found in smooth muscle cells (Eddinger and Wolf, 1993; Gaylinn, et al., 1989; Rovner, Murphy and Owens, 1986). These isoforms are encoded by different genes (Katsuragawa, et al., 1989) and are mapped to different chromosomes from the smooth muscle MHCs (Matsuoka, 1993). However, the localization and the function of the NM MHCs in smooth muscle cell is unknown.

The two 17 kD myosin light chains (MLC<sub>17a</sub> and MLC<sub>17b</sub>) found in smooth muscle have been identified to be the products of a single gene by alternative splicing (Nabeshima, et al., 1987). MLC<sub>17a</sub> is the more acidic isoform and MLC<sub>17b</sub> is the more basic one. The ATPase of myosin is lower in proportion to the relative expression of MLC<sub>17b</sub> (Helper, et al., 1988) and the maximum shortening velocity estimated from zero load is inversely proportional to the relative amount of MLC<sub>17b</sub> (Malmqvst and Arner, 1991). The regulatory smooth muscle light chain (MLC<sub>20</sub>, 20kD) and nonmuscle light chain expressed in smooth muscle are highly conserved among species and there are no reports suggesting that isoform variants affect function (Somlyo, 1993).

**Tropomyosin** is another important protein of the thin filament. Tropomyosin molecules lie in the groove of actin helix and consist 284 amino acids (Clayton, et al., 1988). Tropomyosin is a dimer of two coiled-coil polypeptide chains with close to 100%  $\alpha$ -helical content, binds end-to-end along actin and thereby imparts coopereativity to the regulation of contraction. Two subunit isoforms have been found in smooth muscle, the acidic isoform and the basic one. In addition to isoelectric points, their molecular weights are slightly different as well (Fatigati and Murphy, 1984). The subunit composition of tropomyosin remained in

question although it has been known for sometime that smooth muscle tropomyosin contains about 50% of each isoform (Cummins and Perry, 1974). Reports from *in vitro* studies showed evidence both for homodimers (Graceffa, 1989) and for the heterodimer (Sanders, et al., 1986). More recently, Jancsó and Graceffa (1991), using anion-exchange chromatography and native gel electrophoresis techniques, demonstrated that the native protein is composed of more than 90% heterodimer. Although tropomyosin heterodimer composition predominates in several smooth muscle types, its functional significance is not clear.

#### Previous Knowledge on Myogenic Reactivity

A general introduction to myogenic phenomenon and its physiological importance, smooth muscle contraction and contractile proteins in smooth muscles has been provided in the previous parts of the chapter. Although smooth muscle studies have made many breakthroughs during the past decades, many gaps still remain in our understanding of myogenic reactivity. For example, little is known about the cellular basis for this phenomenon regarding what is sensed, what is controlled, what are the involved signal transduction pathways and how they contribute to this vasoregulatory event. The following section will summarize previous studies related to arteriolar myogenic response.

#### *Wall Tension as the Sensing Parameter?*

A tension sensor has been suggested as the mechanosensor involved in arteriolar myogenic reactivity (Johnson, 1980). According to this hypothesis, it is the increase in wall tension, not pressure, that induces vessel constriction. This constriction leads to a reduction in wall tension (according to Laplace relationship) and thereby inhibits any further constriction.

The apparent effect of this negative feedback system is that vessel diameter is regulated against changes in transmural pressure. The pressure- or stretch-increased smooth muscle sensitivity to agonist stimulation (Meininger and Faber, 1991; Lombard, et al., 1990) can also be explained by the increase of tension. A recent study from VanBavel and Mulvany (1994), using rat mesenteric artery, gave more support to this proposal. With an automatic feedback adjustment system, they were able to test the arterial responsiveness to agonists under isometric as well as isobaric conditions. They found that isometric vessels were significantly more sensitive to norepinephrine and vasopresin than isobaric vessels. Similar results were reported by Bevan and colleagues (Dunn, et al., 1994) in isolated rabbit mesenteric vessels. However, how the vessel wall tension is sensed and how the signal is converted to smooth muscle contraction is unknown.

#### *Endothelial Modulation of Myogenic Reactivity*

It is now generally agreed that myogenic reactivity is a characteristic of the smooth muscle cells (Meininger and Davis, 1992). Although some studies suggest endothelial cells play a crucial role in arteriolar myogenic response (Harder, 1987; Katusic, et al., 1987; Rubanyi, 1988), the particular experimental conditions and protocols involved in these studies might not be physiological. For example, removal of endothelium with enzymes such as elastase and collagenase appears to damage the underlying vascular smooth muscle cells. Further, Liu et al. (1994) showed that even a nonchemical method for endothelium removal, air perfusion, can still damage dog kidney arteries and hence impair myogenic responsiveness, providing more evidence for the idea that inhibition of myogenic reactivity is due to the damage of smooth

muscle cells rather than loss of endothelium. Convincing evidence has been accumulated showing that an intact endothelium is not required for normal myogenic reactivity of the vessel and that the removal of the endothelial layer does not change basal tone and myogenic responsiveness (Bulow and Nilsson, 1991; Falcone, et al., 1991; MacPherson, et al., 1991; McCarron, et al., 1989). However, the endothelium may indeed play a possible role in modulating myogenic reactivity (for review see Kuo, et al., 1992). For example, in response to shear stress caused by blood flow, endothelial cells may release vasoactive compounds such as substance P, EDRF (Endothelium Derived Relaxation Factor, now identified to be nitric oxide) or prostaglandins, which modulate guanylate or adenylate cyclase activity in vascular smooth muscle. Also noticed was that most of the studies suggesting that endothelium play a crucial role came from those performed on cerebral arteries. It is possible that the control of blood flow or capillary pressure is more efficient and essential in brain and that it requires the involvement of both endothelial and smooth muscle cells. Another possible explanation to the discrepancy regarding the role of endothelium would be species or tissue specific differences.

#### *Proposed Mechanisms for Myogenic Reactivity*

It is well known that in isolated arterial/arteriolar preparations removal of extracellular  $\text{Ca}^{2+}$  will eliminate myogenic responsiveness (Harder, et al., 1987; Jackson and Duling, 1989). Davis, Meininger and Zawieja (1992) demonstrated that stretching of the isolated pig coronary arterial smooth muscle cells results in an increase in  $\text{Ca}^{2+}$  influx which occurs in part via a nifedipine-resistant pathway. This pathway has been identified to be a SAC (Davis, Donovitz

and Hood, 1992), hence suggesting that stretch activated  $\text{Ca}^{2+}$  influx may, in part, account for pressure-induced activation of intact blood vessels.

Membrane depolarization has been observed in isolated dog renal artery and cat cerebral artery preparations (Harder, 1984; Harder, et al., 1987) as well as in ferret trachealis smooth muscle (Coburn, 1987). Also, VOCs are considered to be implicated in calcium entry during arteriolar myogenic reactions (Harder, et al., 1987, Hill and Meininger, 1994). Using rabbit facial vein, which demonstrates stretch-induced as well as temperature-sensitive tone, Laher and Bevan (1989) found that the stretch-induced smooth muscle tone is associated with increases in  $\text{Ca}^{2+}$  influx,  $[\text{Ca}^{2+}]_i$ , and MLC phosphorylation. However, none of these parameters were further increased while this stretch activated tone was potentiated by PKC, hence, indicating an increasing sensitivity in contractile apparatus to  $\text{Ca}^{2+}$  following PKC activation (Laporte, et al., 1993). The idea of PKC involvement in arteriolar myogenic reactivity has been reported by several investigators. For example, Hill et al. (1990), using both *in vivo* and *in vitro* preparations of rat cremaster arterioles, demonstrated that inhibitors of PKC attenuated the myogenic response to pressure increase while a PKC activator, indolactam, enhanced it.

$\text{Ca}^{2+}$  release from intracellular stores has been reported following a mechanical stretching on porcine coronary arterial smooth muscle (Tanaka, et al., 1993 and 1994). This stretch induced  $\text{Ca}^{2+}$  release is believed to be mediated by  $\text{IP}_3$ . Evidence supporting this idea also comes from studies demonstrating that stretch can activate PLC activity in vascular smooth muscles (Matsumoto, et al., 1995; Osol, et al., 1993). It is reported that PLC activity is significantly increased in rabbit aortic muscle within 200-300 ms post-stretch and  $\text{Ca}^{2+}$  influx

via gadolinium-sensitive ion channels is involved in this PLC activation (Matsumoto, et al., 1995). Increased PLC activity has also been noticed during pressurization in isolated renal arteries (Narayanan, et al., 1994). However, the studies of Matsumoto were performed on conduit vessels which do not typically contract to increases in intraluminal pressure while the results from Narayanan et al. were acquired 15 minutes after the pressure increase, a time point that would be expected to reflect only steady state conditions.

Increases in MLC phosphorylation have been reported after a mechanical stretch of arterial and non-vascular smooth muscles (Barany, et al., 1990; Csabina, et al., 1986), indicating an activation of MLCK following stretch. However, the experimental approaches in their studies, e.g. stretching of the smooth muscle strips to about 1.7 times their resting lengths, were not physiological stimulations and therefore, the results may not reflect an *in vivo* situation.

Based on the known knowledge, possible cellular mechanisms involved in the vascular myogenic response were proposed by Meininger and Davis (1992). According to their suggested scheme of events, stretch of vascular smooth muscle acts principally at the cell membrane to alter ion conductance and perhaps initiate hydrolysis of membrane phospholipids. While the stretch induced breakdown of membrane phospholipids may produce sufficient  $IP_3$  to release  $Ca^{2+}$  from intracellular stores, the change in membrane ion conductance increases influx of  $Na^+$  and  $Ca^{2+}$  through SACs. This influx of cations results in membrane depolarization which in turn activate  $Ca^{2+}$  VOCs augmenting  $Ca^{2+}$  influx.  $Ca^{2+}$  entered through SACs could directly initiate contraction or act to trigger  $Ca^{2+}$  release from internal stores. The increased  $[Ca^{2+}]_i$  then

is assumed to activate MLCK which leads to contraction. Concomitant activation of PKC, through DAG generated by phospholipid hydrolysis, is hypothesized to initiate a  $\text{Ca}^{2+}$  sensitizing mechanism.

### Aims of the study

The background material provided in the previous section gives a brief overview of arteriolar myogenic responsiveness, including its role in local microvascular blood flow autoregulation, and mechanisms underlying vascular smooth muscle contraction. However, it is apparent that comparatively little is certain as to the actual intracellular biochemical pathways which lead to the generation of basal microvascular tone and the ability to adjust arteriolar diameter appropriately in response to changes in intraluminal pressure. Thus a major goal of the studies described in this thesis is to extend our mechanistic knowledge of vascular smooth muscle contraction to the level of the microvasculature. Such studies are of direct physiologic significance as the microvasculature represents a major site for the control of peripheral vascular resistance and the control of local blood flow and pressure. Further, the data are required for our full understanding of pathophysiologic states affecting the microcirculation, such as hypertension and diabetic microangiopathy, and may provide potential avenues for development of rationale pharmacological intervention.

As can be appreciated from the background section above contraction of vascular smooth muscle is a complex process with some uncertainty as to the exact cellular and molecular mechanisms which give rise to contraction. Variation in functional properties of smooth muscle cells in different tissues may result from a number of factors including

differences in either 1) the structural composition of proteins participating in the contractile process; or 2) the underlying signaling pathways. These two alternatives represent both a long-term (through structural composition) and a rapid (short-term generation of signaling molecules) mechanism for regulating arteriolar smooth muscle contractile function. To date, few studies have been performed on arteriolar smooth muscle cells regarding the contractile protein composition aspect. Our knowledge of contractile protein isoform expression and mechanisms for smooth muscle contraction is largely derived from studies of conduit vessels and non-vascular smooth muscles. Further, whether the generally accepted or “textbook” mechanism for smooth muscle contraction -  $\text{Ca}^{2+}$ /CaM activated MLC phosphorylation - is an obligatory requirement for the generation of arteriolar tone and myogenic reactivity is not known. Therefore, the specific aims of this study were to test the hypotheses that:

1. *Contractile protein isoforms vary between vessels of different sizes with the contractile isoforms exist more abundant in more active vessels.* These studies are described in Chapter 3 and, in addition to describing contractile protein isoforms in small arterial vessels, they provided the basis for establishing electrophoretic techniques for measurement of arteriolar myosin light chain phosphorylation which was used in subsequent sections.
2. *Pressure-dependent steady-state arteriolar myogenic tone is dependent on  $[\text{Ca}^{2+}]_i$  and MLC phosphorylation:* These studies detailed in Chapter 4 were conducted to establish whether arteriolar tone is dependent on the generally accepted mechanism for smooth muscle contraction, i.e.  $\text{Ca}^{2+}$ /CaM/MLCK mediated phosphorylation of the myosin regulatory light chain. This data was required before considering the possibility of an

obligatory involvement of non-classical contractile mechanisms (e.g. involvement of protein kinase C) or examining temporal aspects of the  $\text{Ca}^{2+}$ /phosphorylation signaling pathway.

3. *The myogenic contraction to an acute pressure increase is  $[\text{Ca}^{2+}]_i$  and MLC phosphorylation dependent and that the temporal changes in these parameters will exhibit a distinct pattern compared to that occurring during an agonist-induced contraction.*

These studies described in Chapter 5 were designed to extend the steady-state data and, in particular, examine whether there was apparent dissociation between the diameter response and  $\text{Ca}^{2+}$ /MLC phosphorylation levels during the time course of the contraction.

Comparisons with the response to the  $\alpha_1$ -adrenergic agonist, norepinephrine, were included as a larger database exists in the literature for agonist-induced smooth muscle activation than for activation in response to mechanical stimuli.

4. *The  $\text{Ca}^{2+}$  requirements for basal arteriolar tone and acute myogenic reactivity are met through a combination of  $\text{Ca}^{2+}$  entry from the extracellular environment, release from intracellular stores and  $\text{Ca}^{2+}$  sensitization processes.* These studies described in Chapter 6 were performed to address the question of the source of activator  $\text{Ca}^{2+}$  (e.g. extracellular compared with sarcoplasmic reticulum) that is required for basal tone and acute myogenic responses. As in the previous chapter comparisons were made between the pressure-induced response and that occurring after exposure to norepinephrine to facilitate interpretation of the data in context of the available literature. Further, the use of pharmacological agents such as L-type  $\text{Ca}^{2+}$  channel blocker (verapamil) and compounds

acting on the sarcoplasmic reticulum (caffeine, ryanodine) was exploited to manipulate the  $\text{Ca}^{2+}$  supply.

While the studies relating to these aims are described in individual chapters an overall discussion is provided in Chapter 7 to address the general question of regulation of arteriolar tone and myogenic reactivity via mechanisms involving intracellular  $\text{Ca}^{2+}$  and contractile protein modification.

## CHAPTER II

### MATERIALS AND METHODS

The general methods used in the studies are described below. Specific methods and protocols are included in the individual chapters.

#### Animal Preparation

Studies used male Sprague-Dawley rats between 6-9 weeks of age, weighing 200~350 grams. Rats were housed in a temperature and humidity controlled facility with a 12 hour light/dark cycle. Before use in experiments rats were allowed free access to a standard rat chow diet and drinking water. Use of animals was approved by the Animal Care Use Committee at Eastern Virginia Medical School.

Prior to vessel isolation, rats were anesthetized with sodium thiopental (Pentothal, 20mg/100g body weight) administered by a single intramuscular injection on the outer hind leg. If a surgical plane of anesthesia was not reached, a second supplementary dose of anesthetic [subcutaneous injection of ~0.1ml of the drug (100mg/ml in saline)] was administered.

#### Preparation of tissues and cannulating glass micropipette

Small mesenteric arteries and cremaster muscle first order arterioles were used in the described studies. While cremaster arterioles have been used in earlier studies by the mentor (Hill, et al., 1990; Hill and Meininger, 1994) and showed strong myogenic reactivity,

mesenteric arteries were chosen due to their size, ease of accessibility and that electrophoretic separations can be performed on single vessel segments. It is important to note that cannulated small mesenteric arteries are also capable of exhibiting spontaneous tone and myogenic reactivity. Figure 2-1 shows illustrations of rat mesenteric and cremaster vascular beds with arteries and arterioles labeled.

*Cremaster arterioles* Anesthetized rats were placed on a plastic dissecting board and held in position with tapes. Cremaster muscles were removed in the anesthetized state (as compared to post mortem for mesenteric vessels) to ensure that the vessels contained a blood column which facilitates visualization of the vessels for dissection. Cremaster muscle(s) was opened and separated from skin by gently pulling off the connective tissues with tweezers. Then the muscle(s) was removed by disrupting the connective tissue fascia, which joins the cremaster muscle to the epididymis and testis, and transferred to a dissection chamber containing a cold ( $<4^{\circ}\text{C}$ ) buffer solution [3mM 3-(N-morpholino)-propane-sulfonic acid (MOPS), 145mM NaCl, 5mM KCl, 2mM  $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ , 1.2mM  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ , 1.4mM  $\text{NaH}_2\text{PO}_4$ , 0.02mM EDTA, 2mM pyruvate, 5mM glucose and 1% albumin]. The cremaster muscle was allowed to equilibrate in the chamber for 15-20 minutes before starting arteriole dissection.

*Small mesenteric arteries* Immediately before opening the abdomen, rats were killed by cervical dislocation. This is to prevent over-bleeding when dissecting out mesentery. Through an abdominal cut, rat mesentery was spread over saline (0.9% NaCl solution) wet gauze pads and kept moist with cold saline. Part of the mesentery was removed by carefully cutting along the small intestine (the 4th order arteries run parallel along the intestinal wall while the 5th

Figure 2-1. Illustration of rat mesenteric (top) and cremaster (bottom) vascular bed. The rectangular frame on the cremaster muscle indicates where the vessel segment is usually taken from.

order vessels typically penetrate the gut wall). Then the mesentery was transferred to the dissecting chamber and equilibrated for 15-20 minutes as was done for cremaster muscle.

*Cannulating pipette preparation* Glass tubes (o.d. 0.047", i.d. 0.040", Drummond Scientific Company, PA.) were first pulled with a Sachs Flaming Micropipette Puller (Model PC-84, Sutter Instrument, CA) to form a tapering tip. Then the tip was shaped and polished with the use of a microforge manipulator (Stoelting Co.) to the final form.

Figure 2-2. Illustration of glass micropipette (top) and a cannulated vessel (bottom).

#### Isolation and Cannulation of Single Arterioles

Dissection was performed with the aid of a dissecting microscope (Olympus, Japan). The chamber was illuminated with a Fiber-LiteR high intensity illuminator (model 180, Dolan Jenner Industries Co.). To prevent tissue from moving during the dissection, cremaster muscle or mesentery was pinned onto the silicon layer covering the bottom of the chamber with #27 needles. The silicon layer was made from a 184 Silicone Elastomer Kit (Dow Corning Corp.,

MI). Vessels were cleared from surrounding tissues using ultrafine microsurgical instruments (Fine Science Tools, Inc., CA). Arteriole segments were then cannulated, secured with 10-0 nylon suture (Alcon Surgical Inc. TX), onto glass micropipettes and mounted in a custom designed microperfusion system as shown in figures 2-2 and 2-3. The perfusion system was then transferred to the stage of a Nikon Diaphot microscope coupled to a high resolution video system comprising of a CCD camera, a video recorder, a time/date generator, and a display monitor. Vessels were gradually warmed to 34-35°C for cremaster arteriole, and 36-37°C for mesenteric arteries, and allowed to develop spontaneous tone while slowly pressurized to a level expected in vivo (70mmHg for cremaster first order arteriole and 90mmHg for small mesenteric arteries). During experiments vessels were superfused with Krebs Ringer bicarbonate buffer solution [111mM NaCl, 25.7mM NaHCO<sub>3</sub>, 4.9mM KCl, 2.5mM CaCl<sub>2</sub>, 1.2mM MgSO<sub>4</sub>, 1.2mM KH<sub>2</sub>PO<sub>4</sub>, 11.5mM Glucose, and 10mM N-2-hydroxyethylpiperazine-N'-2-ethane-sulfonic acid (HEPES)] maintained at physiologic conditions with respect to temperature, pH, pO<sub>2</sub> and pCO<sub>2</sub>. To be considered viable and suitable for study, arterioles needed to exhibit spontaneous tone, myogenic responsiveness and be free of pressure leaks.

#### Method for studying Myogenic and Agonist Responses in Isolated Arterioles

Intraluminal pressure in the isolated arteriolar segment was controlled by adjusting the height of a fluid reservoir which was connected via polyethylene tubing to one of the cannulating pipettes. All experiments were performed in the absence of intraluminal flow to enable responses to transmural pressure to be studied without shearing forces. To quantitate the response of an arteriole to a given change in transmural pressure or to agonist

Figure 2-3. Illustrations of vessel cannulation and cannulating chamber.

stimulations, vessel lumen diameter was measured directly on the video monitor using a calibrated electronic caliper (Made by the Microcirculation Research Institute, Texas A&M University, TX). Experiments were videotaped for subsequent analysis when necessary.

#### Intracellular $\text{Ca}^{2+}$ Measurement with Fura-2 in Isolated Arterioles

Due to the pivotal importance of  $\text{Ca}^{2+}$  in cellular signal transduction, many techniques have been developed to measure the  $[\text{Ca}^{2+}]_i$ , among them is the fluorescent indicators. Fura-2 is currently the most popular  $\text{Ca}^{2+}$  indicator for microscopic studies. Upon  $\text{Ca}^{2+}$  binding, its excitation spectrum shifts approximately 30nm towards shorter wavelengths while the green emission from fura-2 maintains its peak at 505-520nm. A diagram showing the excitation spectrum of fura-2 is given in figure 2-4. Therefore, the ratio of fluorescence emission intensities obtained from 340/380nm excitation pair provides a measure of  $[\text{Ca}^{2+}]_i$  which is generally unaffected by variable dye content or cell thickness (Tsien, 1989). Fluorescent emission does not change with  $\text{Ca}^{2+}$  binding when excited at 360nm.

The acetomethoxy ester form of fura-2 (fura-2 AM, 50 $\mu\text{g}/\text{vial}$ , Molecular Probes, OR) was dissolved in DMSO (50 $\mu\text{l}$ , final concentration 0.5%) and then diluted in Krebs bicarbonate buffer (10 ml) containing 0.01% Pluronic F-127 (1 mg, Molecular Probes, OR) to facilitate dispersion and loading of the dye. The cell-permeant AM ester passively crosses the plasma membrane, and once inside the cell, is cleaved to a cell-impermeant product by intracellular esterases. Pluronic also helps to prevent the compartmentalization of fura-2 (information sheet on AM esters, Molecular Probes, Inc.). Arterioles were loaded with 5 $\mu\text{M}$  fura-2, applied to the exterior of the vessel, for 60 minutes at room temperature. Lowering the loading temperature

Figure 2-4. Excitation spectra of fura-2.

was to reduce the possibility for compartmentalization of fura-2. Under these conditions, abluminal application of fura-2 has been shown previously (Meininger, et al., 1991) to restrict loading to the smooth muscle layer without substantial access to the endothelium. Loading was followed by an extensive washout, 30 minutes, using Krebs bicarbonate solution. Excitation was provided by a 75W Xenon light source directed through a quartz collector lens then passing through either a 340nm or a 380nm (or 360nm when doing  $Mn^{2+}$  quench experiments) filter; excitation wavelength was controlled by a computer driven wheel (Metaltek Instruments, NC) positioned between the light source and the microscope. A dichroic mirror reflected the excitation wavelengths through an appropriate fluorescence objective (Fluor 20X, Nikon) to the vessel segment. Fluorescence emission from the sample

was passed through a bandpass filter to an intensifier (Videoscope International, Ltd.) and a CCD camera (Hamamatsu, Japan). Fluorescence intensities of the 340nm and 380nm excitation images in addition to the 340/380nm ratio were quantitated using a fluorescence image analysis system (Image 1 /FL, Universal Imaging Corp. PA). Figure 2-5 shows a schematic diagram of the computerized  $\text{Ca}^{2+}$  measurement system used in the study. A background image was taken after the system was set up in each experiment and experimental data was obtained by subtracting the background from acquired images. For each collection time point, 8 frames of images were averaged for each excitation wavelength. The microscope was focused on the outer sections of the vessel wall to maximize the contribution of the vascular smooth muscle while further minimizing any contribution from the endothelium. Previous studies from Meininger, et al. (1991) indicated that de-endothelialization of fura-2 loaded arterioles did not result in a significant alteration in  $\text{Ca}^{2+}$  related fluorescence.

Vessel diameter can also be measured from the fluorescence images using the pixel count of a region, that covers the entire vessel diameter, as an index. This measurement is illustrated in figure 2-6: as the vessel diameter changes the pixel count of the region changes accordingly. The effect of region height is canceled out when the results are expressed as relative change. Therefore, the pixel count changes, when presented as percent of basal, reflect the relative changes in vessel diameter. This function of the image system provides a practical way for simultaneous diameter measurement especially during experiments when rapid responses, such as those to NE stimulation, are expected. This method has been reported in studies by other investigators (Meininger, et al., 1991).

**Figure 2-5. Schematic diagram of the  $\text{Ca}^{2+}$  measurement system.**

Figure 2-6. Measurement of vessel diameter using pixel count as an index. As shown in the figure, only the shaded area in the region is counted and therefore it provides an indication of changes in vessel outer diameter.

To enable continual viewing of the vessel segment, while periodically taking  $\text{Ca}^{2+}$  measurements, a transillumination ( $>600\text{nm}$ ) light source coupled to a separate CCD camera and video monitor was used. This procedure did not interfere with the fluorescence measurements.

#### Calibration of the $\text{Ca}^{2+}$ measurement system

While  $\text{Ca}^{2+}$  data was generally considered in terms of change in the fluorescence ratio ( $R_{340/380\text{nm}}$ ), *in situ* calibrations were also performed.

$R_{\min}$  was determined by exposing the vessel segments to 2mM EGTA in Krebs buffer containing 0mM  $\text{Ca}^{2+}$ . The fluorescence emission was monitored every two minutes following the buffer change until  $R_{340/380\text{nm}}$  stabilized, and that value was taken as  $R_{\min}$ .

$R_{\max}$  was determined by exposing preparations to 4-bromo-calcium ionophore-A23187 (15 $\mu$ M, Sigma, MO) or ionomycin (14 $\mu$ M, Calbiochem, CA) in normal Krebs buffer containing 2.5mM  $\text{Ca}^{2+}$ . The peak value observed during the following measurement was taken as  $R_{\max}$ . It was noticed that the  $\text{Ca}^{2+}$  rise was rapid and transient.

These values were used in the equation formulated by Grynkiewicz et al. (1985):

$$[\text{Ca}^{2+}]_i = K_d * (R - R_{\min}) / (R_{\max} - R) * b \quad (2-1)$$

where R is the measured ratio of 340/380nm; b is the ratio of the fluorescence intensity at 380nm in 0mM  $\text{Ca}^{2+}$  to that in 2.5mM  $\text{Ca}^{2+}$ ;  $K_d$ , the dissociation constant, was assumed to be 224.0nM in our situation. The measured values, with calibration using 15 $\mu$ M bromo-A23187, used in the calibration equation were  $R_{\min} = 0.27$ ,  $R_{\max} = 2.02$  and  $b = 0.92$ .

To assure the precision measurement of  $[\text{Ca}^{2+}]_i$ , the absorption spectra of the optical filters used in the experiments (340nm, 360nm, and 380nm) were checked (Figure 2-7). The shift of 360nm filter spectrum towards shorter wavelength may account for the fluorescence intensity increase detected with the filter during the  $\text{Mn}^{2+}$  quench experiments.

#### Preparation of Samples for Electrophoretic Protein Separation

For samples that were used to measure protein isoform expression, the vessel segments were transferred to appropriate sample buffers immediately after dissection. Mesenteric tissues and samples of conduit vessels were usually ground using glass microhomogenizer (Wheaton, NJ). 2-D samples were kept cold, in ice/water mixture, while grinding because excessive heat will cause urea to covalently modify proteins producing erroneous charge modifications. For

Figure 2-7. Absorption spectra of the optical filters.

the same reason, homogenization time had been limited to less than one minute when possible. 1-D samples (for separation of myosin heavy chain isoforms) were then heated in boiling water for 10 minutes to facilitate protein denaturation. Control experiments were also done without heating the sample, and it appeared that this step may be omitted.

In several studies, samples of possible contaminating tissues (adipocytes, red cells, plasma) were collected and similarly prepared for electrophoresis. Platelet homogenates were prepared from whole rat blood to provide a tissue sample expected to contain only non-muscle forms of myosin heavy chain and as such was used as a control. To assess the possible contribution of endothelial cells, actin and myosin heavy chain isoforms were also examined in vessels from which the endothelium had been removed. Endothelial removal was accomplished by introducing a glass micropipette into the vessel and physically abrading the luminal surface (Kuo, et al., 1990), after which the lumen was flushed with fresh buffer. Vessels prepared in such a manner 1) do not exhibit functional endothelium-dependent vasomotor responses and 2) have been shown histologically to be lacking an intact endothelial cell layer.

Collection of samples for myosin light chain phosphorylation measurements required more extensive preparation. After the initial set up, as described in previous sections, the arteriolar segments were treated according to the experimental protocols. At the appropriate time point, they were lifted above the superfusate by quickly turning the knob on the custom made chamber (refer to figure 2-8 for chamber structure), frozen with a pair of acetone/dry ice cooled tongs and transferred immediately to the acetone/dry ice slurry. This procedure promptly stops enzymatic reactions in the vessel and the subsequent measurement reflects the

**Figure 2-8. Illustration of the cannulating chamber for vessel sample collection.**

Top View of the Cannulation Chamber

situation when the vessel was frozen (Aksoy, et al., 1983). As the vessel was slowly warmed up to room temperature, acetone replaced the water in the vessel and the dehydration maintains enzymes in an inactive state. The end portions of the vessel, distal to the ties, were eliminated from the sample as they were considered damaged during cannulation and would potentially interfere with the measurements. Then the vessel was transferred to an homogenizing buffer and subjected to sonication (Branson ultrasonic cleaner, Branson Cleaning Equipment Co., CT) for 10 minutes to extract proteins. Usually, 2-3 vessel segments (approximately 1cm in total length) were needed to provide sufficient tissue for one measurement.

Vessel samples were homogenized in buffer appropriate to the electrophoretic techniques being used: samples to be used for two dimensional (2-D) gel electrophoresis were homogenized in a solution containing 8M urea, 20mM dithiothrietol (DTT), and 2% Triton X-100 (Pierce, IL); samples for separation of myosin heavy chains using 1-D gel were homogenized in 1% SDS, 15% glycerol, 62.5% Tris-base, 15mM dithiothrietol and 0.01% bromophenol blue (P. H. Ratz, personal communication).

Protease inhibitors were not routinely included in the homogenization buffers as it has been shown that rapid homogenization in such buffers is sufficient to prevent proteolysis (Rovner, Thompson and Murphy, 1986). Further, our own preliminary studies indicated that once homogenized in these buffers proteolytic degradation could not be detected, even upon exposure of the samples to conditions which might be expected to enhance proteolytic breakdown (e.g. room temperature storage for several hours prior to freezing). All of the sample homogenates were kept at -80°C before subjected to gel electrophoresis.

### Electrophoretic and Western Blotting Techniques

Isoelectric focusing (IEF) and sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) were used for protein separation. The mini-protein II gel system from BioRad (CA) was employed. The two dimensional (2-D) gel electrophoresis methods were mainly adopted from the studies of Driska et al. (1981) with some modification by Ratz and Murphy (1987) which has been considered a classical method for detecting MLC phosphorylation.

Actin and tropomyosin isoforms as well as phosphorylated myosin light chains were separated by 2-D gel electrophoresis. Isoelectric focusing was performed using a 4% acrylamide tube gel containing an Ampholyte range of 4.5-5.4 pH units. Gels were run at 750V for 3.5 hours after a 10-minute focusing at 500 V. The proteins were then subjected to the second dimension separation by molecular weight on a Laemmli style (Laemmli, 1970) slab gel (3.5% stacking gel and 12 or 15% separating gel). The electrophoretic condition was constant voltage at 200 V for 45 minutes. Myosin heavy chain isoforms were separated using one dimensional gels (3.5%, Laemmli style) or Giulian glycerol gels (Giulian, et al., 1983) containing 12% acrylamide and 10% glycerol. These gels were run at a constant current of 30mA for 2 hours or 40 mA for 18 hours, respectively; resolution was found to be similar in both systems. Sample loadings were optimized for the particular protein isoforms under study. Figure 2-9 shows a representative 2-D gel for MLC separation.

**Figure 2-9. Representative gel showing the separation of myosin light chain isoforms.**

After electrophoresis, the proteins were treated differently according to the expected protein loading. For the study of myosin light chain phosphorylation, the proteins were stained with silver using BioRad Silver Stain Plus Kit. Heavily loaded samples (i.e. those for actin, tropomyosin and myosin heavy chain isoforms) were stained with Coomassie Brilliant Blue R-250. Quantitation was performed using line scan densitometry subroutine of a video based image analysis system (Image 1, Universal Imaging, PA). Results were expressed as percent of the isomer in a given protein.

Western blot techniques were performed for immunochemical identification of different actin, myosin and tropomyosin isoforms. After gel electrophoresis, proteins were transferred from gels to nitrocellulose transfer membranes (NitroPlus, 0.22 $\mu$ m, Micron Separations, Inc., MA) using a BioRad Mini Trans-Blot Electrophoretic Transfer Cell. Blottings were carried out in a cold transfer solution (Towbin, et al., 1979) at 100 V for 1 hour with continuous mixing. Horse radish peroxidase conjugated secondary antibodies were always used and the staining was produced using 4-chloro-1-naphthol (Pierce, IL).

#### Statistical Methods and Data Analysis

Based on previous experience using isolated vessel preparations it was necessary to achieve approximately 6 successful experiments for each of the manipulations described under experimental components. Where appropriate, i.e. when considering normally distributed data, simple comparisons of the mean and standard errors were performed using a two-tailed Student t-test. When considering data which is not normally distributed, levels of significance were determined by non-parametric statistics, e.g. Mann-Whitney U test. When multiple

comparisons were to be made significance was determined using analysis of variance (Student-Newman-Keuls). Paired comparisons were applied when analyzing results from the same vessel with different treatments. For all comparisons significance was assumed at the  $p < 0.05$  level. Data handling was performed using an IBM compatible computer (Gateway 2000, 486DX33) with appropriate spreadsheet (Microsoft Excel), graphical (SigmaPlot for Windows 5.0) and statistical (Instat) programs.

### **CHAPTER III**

## **CONTRACTILE PROTEIN ISOFORM EXPRESSION ALONG RAT MESENTERIC VASCULAR TREE**

It is well established that variation in contractile agonist sensitivity exists between different blood vessels. In particular, there is a tendency toward increased agonist sensitivity as arterial/arteriolar diameter decreases along the vascular network (Duling, et al., 1968 and Gore, 1972). Further, the existence of spontaneous vascular tone and the ability to control vascular resistance through local autoregulatory mechanisms (e.g. myogenic reactivity) largely resides in the small arterial vessels rather than the larger conduit arteries (Davis, 1993, Sun, et al., 1992).

While it is conceivable that such differences in function relate to variation in receptor populations or signal transduction mechanisms it is also possible that there are fundamental differences at the level of the contractile apparatus. This possibility is supported by the existence of a number of isoforms of the various contractile proteins (for review see Murphy, 1992 and Somlyo, 1993). Although the functional significance of many of these protein variants is uncertain, studies have shown that contractile protein isoform expression can be modified according to physiological and experimental situation (Babij, et al., 1992; Morano, et al., 1992), suggesting that smooth muscle can express isoforms appropriate for a given set of conditions. Further, there is evidence for developmental changes in the distribution of contractile proteins (Eddinger and Murphy,

1991; Zanellato, et al., 1990). It is also apparent that differing smooth muscle can exhibit a different complement of specific isoforms. For example, Fatigati and Murphy (1984) demonstrated that muscle specific  $\alpha$ -actin form was more abundant in arteries compared to veins.

The present study examined 1) whether it was feasible to use electrophoretic techniques to separate and quantitate the major contractile protein isoforms that exist in small arterial vessels taken along the mesenteric vascular arcade and 2) whether evidence exists to support the suggestion that contractile function may relate to particular isoform expression. Knowledge of whether or not there is variation in contractile protein isoform expression along the vascular tree is required before the relationship between specific protein isoforms and reactivity can be systematically addressed.

#### Materials and Methods

Tissues were prepared as described in chapter 2. For the studies involving separation of myosin heavy chain isoforms, samples of rat aorta and femoral artery were also prepared to examine regional variations in isoform expression. In addition, samples of hog carotid artery (21 days of age, n = 9) were also examined; the rationale for studying this vessel was that its myosin isoforms are well characterized in the literature (Eddinger and Murphy, 1991; Rovner, Thompson, and Murphy, 1986) and as such provided a suitable control.

Polyacrylamide gel electrophoresis was used to separate protein isoforms and the resolution of myosin heavy chains was found to be comparable to that previously described (e.g. Kawamoto and Adelstein, 1987).

To assist in the identification of particular isoforms of myosin heavy chain present in small mesenteric arteries Western blotting procedures were used. Rabbit anti-myosin (SM and NM) antibodies (Biomedical Technologies Inc., MA) and a Goat anti-rabbit IgG-peroxidase (Sigma Chemical Co. MO) were used as the primary and the secondary antibody, respectively.

For two dimensional separation of actin and tropomyosin, samples were loaded at approximately 1  $\mu\text{g}$  actin. This was calculated assuming a tissue density of 1.055  $\text{g}/\text{cm}^3$  and a vascular smooth muscle actin content of approximately 20mg/g tissue in conjunction with the measurements of vessel segment diameter and length (Herlihy and Murphy, 1973).

## Results

Consistent with earlier reports from large vessels, homogenates of the small mesenteric arteries consistently showed that actin stained as three distinct spots (Figure 3-1). Confirmation of the three spots being actin isoforms was obtained using an anti-actin antibody (Sigma Chemical Co.) and Western blotting procedures (data not shown). These isoforms have previously been designated as  $\alpha$ -smooth muscle actin,  $\beta$ -non-muscle actin and  $\gamma$ -actin (mixed smooth muscle and non-muscle). The actin isoform ( $\alpha$ -actin) migrating toward the acidic end of the gel was the most abundant and showed a significant inverse

correlation ( $r = 0.86$ ,  $p < 0.001$ ) with vessel diameter (Figure 3-1). Comparison of 4 arteries subject to endothelial cell removal to 4 size-matched intact arteries suggested that the presence or absence of the endothelial layer did not significantly influence the results. For example,  $\alpha$ -actin content was  $56.3 \pm 2.8$  % of total actin in the intact arteries and  $54.7 \pm 2.9$  % in the denuded vessels.

Compared to the corresponding small veins the arteries showed significantly more  $\alpha$ -actin with a corresponding reduction in  $\beta$ -actin (Figure 3-2). The relative proportion of the two tropomyosin subunits (acidic, basic) did not appear to vary with small artery diameter and as such the data is presented in the form of group data. It can be seen that the tropomyosin subunits were present in approximately equal proportions (Figure 3-3). As described for actin above, confirmation of the two spots being tropomyosin subunits was obtained using an anti-tropomyosin antibody (Sigma Chemical Co.) and Western blotting procedures (data not shown).

One dimensional electrophoretic separations of homogenates of small arteries showed two bands in the region expected for myosin heavy chains (approximately 200kD; Figure 3-4). Consistent with the bands being muscle forms of myosin heavy chain (SM1 and SM2) their electrophoretic mobility was slightly slower than that of the platelet homogenates (Figure 3-4). Co-electrophoresis of artery and platelet homogenates show three distinct bands supporting the proposition that the predominant forms of myosin heavy chain in small mesenteric artery samples were of the muscle type as opposed to the non-muscle type (NM) reported to be present in platelets. Comparison with previously reported studies suggests that the approximate molecular weight of the bands would be

Figure 3-1. Relationship between  $\alpha$  actin content and small mesenteric artery diameter.

Figure 3-2. Comparison of actin isoform content of small mesenteric arteries compared to that of the corresponding small veins. Results are expressed as mean  $\pm$  SEM.

Figure 3-3. Relative abundance of tropomyosin subunits in small mesenteric arteries. As there was no apparent relationship between vessel diameter and content of a particular subunit, results are shown for the total group (n=13).

204kD (SM1), 200kD (SM2) and 198kD (NM) (Murphy, 1993). Western blot analysis using an anti-non-muscle myosin antibody showed a significant reaction with the platelet homogenates and a very faint band in the small artery samples (Figure 3-4). The band detected by the non-muscle myosin antibody in the mesenteric samples appeared to have migrated at a level equivalent to that for the platelet samples and below the coomassie blue stained bands of the 1-D gels (Figure 3-4). Thus, the small mesenteric arteries possess both muscle and non-muscle myosin heavy chains with the muscle forms being far more abundant. No significant relationship was found to exist between small mesenteric artery diameter and the relative amounts of the myosin heavy chain isoforms. Considering the mesenteric arteries as a single group, the ratio of SM1:SM2 was approximately 70:30 ( $n = 18$ ,  $p < 0.001$ ). Comparison of the small mesenteric arteries with samples of conduit vessels (aorta, femoral artery) from animals of similar age showed that there are site-specific differences in the proportion of SM1 and SM2 (Table 3-1). In particular, the highest proportion of SM1 was found in the femoral artery followed by the mesenteric vessels with the lowest proportion in the aorta. As a number of previously reported studies have examined myosin heavy chain expression in hog carotid artery, nine samples of this tissue were also examined. Hog carotid artery was found to contain 62% SM1 compared to 38% SM2.

Comparison of vessel segments with and without an intact endothelium indicated that the myosin heavy chain results were not significantly influenced by the presence of such cells. Separations of homogenates treated in a manner to enhance any proteolytic

Figure 3-4: Digital image, obtained using an Image 1 analysis system (Universal Imaging, PA), showing electrophoretic separation of myosin heavy chains. In the left panel coomassie blue stained sections of acrylamide gel show separation of the heavy chains for a small mesenteric artery homogenate (lane A), a combined small mesenteric artery and platelet sample (lane B) and a platelet homogenate (lane C). It can be seen that the artery separates into two bands (SM1, SM2), the platelet into one band (NM) and the mixed sample into three bands (SM1, SM2, NM). The right panel shows a corresponding Western blot analysis using a non-muscle myosin heavy chain antibody. Marked staining is evident in the platelet and mixed samples indicating that the platelet contains only NM; while the small mesenteric vessel predominately expresses SM1 and SM2, although a very small quantity of NM is seen in the vessel (lane A right panel).

Table 3-1: Myosin SM1 Heavy Chain Content (% total SM MHC)

	RAT			HOG
	Femoral	Aorta	Small Mesenteric	Carotid
Mean	77	65*	70**	62†
SEM	1.3	2.3	2.1	1.8
n	10	11	18	9

\*  $p < 0.05$ , femoral artery vs. aorta; \*\*  $p < 0.01$ , femoral artery vs. small mesenteric artery

† hog carotid artery contains significantly less SM1 (relative to SM2) than does rat femoral ( $p < 0.001$ ) or small mesenteric ( $p < 0.05$ ) arteries.

Significance determined by ANOVA in conjunction with Student-Newman-Keuls test.

degradation (e.g. prolonged room temperature storage) did not provide any evidence to suggest that the more mobile myosin heavy chain band was a breakdown product.

### Discussion

The results of the study provide further evidence for diversity in contractile protein isoform expression between blood vessels. While the exact significance of these proteins variants is uncertain it is tempting to speculate that they contribute to functional variability. In particular, the correlation between  $\alpha$ -actin content (relative to total actin) and mesenteric artery diameter, and that  $\alpha$ -actin is more abundant in small arteries than corresponding veins may be indicative of a relationship between vascular reactivity and contractile protein composition.

Despite the present uncertainty as to the functional significance of many of the contractile protein variants, both *in vivo* and *in vitro* studies have shown that contractile protein isoform expression can be modified under a variety of situations. For example, studies performed on smooth muscles from rats indicate that there are significant developmental changes in contractile protein isoform expression (Eddinger and Murphy, 1991). In particular, there is an increase in the muscle isoforms of actin and myosin heavy chains with a concomitant decrease in the non-muscle protein forms during the first 20 days of life. Cultured vascular smooth muscle cells often undergo phenotypic modulation which results in the cell converting from a contractile to a synthetic state (Fatigati and Murphy, 1984; Owens, et al., 1986). This change in cellular character is associated with a marked decrease in  $\alpha$ -actin expression and a compensatory increase in the  $\beta$ -actin isoform. Similarly cultured saphenous vein smooth muscle cells can be induced to undergo a shift

in myosin heavy chain isoforms such that there is as an increase in the relative amount of the non-muscle isoforms (Seidel, et al., 1991) which is associated with a reduction in cellular contractile activity. Apparent relationships between the contractile protein isoforms expressed and mechanical function is not limited to vascular smooth muscle; for example myosin heavy chain composition of a skeletal muscle fiber correlates with both shortening velocity and maximal force generation (Caizzo, et al., 1992; Emerson and Bernstein, 1987). Thus, these examples and the data from the present study demonstrating a relationship between small artery diameter and relative  $\alpha$ -actin content, and regional differences in the relative amounts of the myosin heavy chain isoforms, provide supportive evidence for the hypothesis that resistance artery reactivity may, in part, relate to protein isoform expression.

A potential source of error in these studies is that the arteries examined are not exclusively composed of vascular smooth muscle but also would be expected to contain, for example, endothelial cells, nerves and connective tissue. Comparison of vessels with a presumably intact endothelium with those subject to a physical denudation procedure suggest that endothelial cells were not markedly contributing to the results. In terms of the distribution of actin isoforms it would be expected that if contamination due to non-muscle tissues had been a significant problem that this would have tended to show as an increase in the non-muscle isoforms ( $\beta$  and  $\gamma$ ) in the smaller arteries. As vascular smooth muscle, itself, can produce the non-muscle isoforms ( $\beta$  and  $\gamma$ ) and that the contractile protein content of non-muscle cells is 1 -2 orders of magnitude less than that of smooth muscle (Murphy, 1992) the contribution of remaining cell types was probably not

significant. The finding of an approximate 50:50 distribution of the tropomyosin subunits is consistent with previous studies in the literature (Gummins and Perry, 1974) and was also taken to be supportive of the reliability of our electrophoretic measurements.

Previous studies have indicated the existence of four myosin heavy chain isoforms; two muscle forms (SM1 and SM2) and two non-muscle variants (NM1 and NM2) (Rovner, Murphy and Owens, 1986). Consistent with results of the present study the major forms present in arteries appear to be SM1 and SM2, although the existence of small quantities of a non-muscle variant in small mesenteric arteries was demonstrated using a Western blotting approach. In apparent contrast to our results from small arteries, Eddinger and Murphy (1991) found that in hog (9 days of age and adult) carotid artery SM1 and SM2 to be present in approximately 77:23 and 55:45, respectively. This difference may well relate to differences in, vessel size, site within the vasculature, developmental stage or species. The data from the present study indicate that significant differences in the ratio of SM1:SM2 exist between different arterial vessels taken from the same rat. Further, as a control we examined a series of hog (21 days of age) carotid artery homogenates which were prepared and separated under the same conditions as the rat samples. Hog carotid arteries were found to have a lower percentage of SM1 relative to SM2 (62%) compared with that found in the various rat samples (65 - 77%) and this value falls in between those described by Eddinger and Murphy [76% for young (6 days) and 56% for adult]. This control value is expected from their study and gives us additional confirmation on our sample preparation and gel electrophoresis techniques.

Boels et al. (1991) reported an increased ratio of SM1:SM2 in pooled samples of guinea pig small mesenteric arteries (diameter approximately 115 $\mu$ m) compared to that in the main branch of the mesenteric artery (diameter approximately 600 $\mu$ m). These authors speculated that the functional significance may relate to increased  $\text{Ca}^{2+}$  sensitivity and hence reactivity of smaller vessels. Our results, however, did not reveal a correlation between mesenteric artery diameter and SM1:SM2 ratio; moreover, a higher ratio was found in the femoral artery. While the differences may relate to the species studied it is possible that results reflect regional differences rather than a relationship with vessel size or branch order.

The electrophoretic data from the present study, obtained under reducing conditions, do not allow conclusions to be drawn as to the composition of the intact myosin molecule. It is of interest to note, however, that Tsao and Eddinger (1993) recently reported that myosin from porcine aorta exists as three species, namely the SM1 homodimer, SM2 homodimer and the SM1-SM2 heterodimer. Further diversity in composition of the intact myosin molecule could be provided by the existence of isoforms of the myosin light chains [e.g. 17,000-dalton light chains (Helper, et al., 1988)]. While these isoforms were not examined in this dissertation, they are of potential significance for future studies.

In summary, the results of this study demonstrate the feasibility of quantitating contractile protein isoforms in small blood vessels using standard electrophoretic techniques. The data presented are, in addition, consistent with the hypothesis that

differences in contractile protein function between vessels may, in part, relate to differences in contractile protein expression.

Additional studies are needed in order to examine the exact functional significance of the particular contractile protein isoforms which are expressed in resistance vessels and to determine whether such expression is developmentally and/or environmentally regulated. These studies, regarding long term regulations of contractile proteins, will require molecular biological techniques, such as RNA extraction and Northern blot. Given the feasibility of using gel electrophoresis for studying biochemical correlates of microvascular smooth muscle function, the remainder of the thesis will, however, focus on the short term regulation of arteriolar contraction. In particular, the role of MLC phosphorylation and  $\text{Ca}^{2+}$  in arteriolar myogenic reactivity will be determined.

## **CHAPTER IV**

### **ROLE OF $\text{Ca}^{2+}_i$ AND MYOSIN PHOSPHORYLATION IN ARTERIOLAR BASAL TONE SETTING**

Resistance vessels are typically characterized by the existence of spontaneous tone (state of partial contraction), the degree of which is dependent on the prevailing intraluminal pressure. This ability of small arterial vessels to develop spontaneous tone is a function of the vascular smooth muscle and as such represents a myogenic property of the arteriolar wall (Johnson, 1980). While the possible contribution of different contractile protein isoforms has been discussed in chapter 3, studies regarding signal transduction aspect of the myogenic reactivity will be reported in this and the following chapters.

While it has generally been assumed that a myosin light chain phosphorylation mechanism contributes to arteriolar myogenic reactivity, the evidence is based solely on studies of conduit arteries (Meininger and Davis, 1992). Further, the exact signaling pathway(s) involved in transducing an intraluminal pressure stimulus into arteriolar contraction remains uncertain. Current evidence indicates that stretch of vascular smooth muscle cells, such as would be expected to occur during an increase in intraluminal pressure, leads to activation of ion channels, increased intracellular  $\text{Ca}^{2+}$  and subsequently contraction. In addition, studies have demonstrated stretch-induced accumulation of the cellular messenger DAG, while indirect evidence has been obtained for a role for protein kinase C in myogenic vasoconstriction (Hill, et al., 1990; Laher and Bevan, 1987; Osol, et

al., 1991). To understand the mechanisms which underlie myogenic reactivity and the setting of basal arteriolar tone, it is critical to determine the involvement of the  $\text{Ca}^{2+}$ -induced myosin light chain phosphorylation pathway.

The aim of the present studies was to determine, in isolated skeletal muscle arterioles the relationship between intraluminal pressure, intracellular  $\text{Ca}^{2+}$  and MLC phosphorylation. In so doing the contribution of MLC phosphorylation to setting of arteriolar basal tone was also ascertained.

#### Methods and Experimental Protocols

Vessel set up,  $\text{Ca}^{2+}_i$  measurement and sample preparation were performed as described in chapter 2. Briefly, isolated rat cremaster first order arterioles were cannulated in a superfusing chamber at a transmural pressure of 70mmHg in the absence of intraluminal flow. Vessels were superfused with Krebs buffer and maintained at 34°C throughout each of the experiments.  $[\text{Ca}^{2+}]_i$  was measured using fura-2 as a fluorescent indicator and fluorescence ratio  $R_{340/380\text{nm}}$  was used for measurement of changes in  $[\text{Ca}^{2+}]_i$ . MLC isoforms were separated by two dimensional polyacrylamide gel electrophoresis. To ensure adequate loading of protein from the microvessel segments it was necessary to pool samples. The separated proteins were quantitated using a computerized image analysis system and MLC phosphorylation expressed as percent phosphorylated MLC of total 20kD MLC. As an index of reproducibility between electrophoretic separations a standard sample of homogenized rat aorta (obtained under conditions of 0 mmHg transmural

pressure) was processed on each day; the extent of phosphorylation was determined to be  $14.5 \pm 0.8 \%$  (mean  $\pm$  SEM),  $n = 7$  determinations.

*Effect of Steady-State Intraluminal Pressure on Arteriolar Wall  $\text{Ca}^{2+}$*

After equilibration and loading with Fura-2, intraluminal pressure was slowly reduced to 30 mmHg after which arteriolar wall  $[\text{Ca}^{2+}]_i$  were measured as pressure was step increased to 50, 70, 100, 120, 150 and 170 mmHg. To ensure steady-state [based on pressure-induced changes in arteriolar diameter observed in earlier studies (Hill, et al., 1990; Meininger and Davis, 1992)], vessels were maintained at each pressure for a minimum of 15 minutes before collection of six 340/380 image pairs at 5 second intervals. In addition to collecting  $[\text{Ca}^{2+}]_i$  data in the active state, arterioles were also examined after being rendered passive by prolonged exposure to 0 mM  $\text{Ca}^{2+}$ /2mM EGTA buffer. Diameter measurements were taken for correlation of  $[\text{Ca}^{2+}]_i$  data with diameter and calculated wall tension.

*Effect of Steady-State Intraluminal Pressure on Myosin Light Chain Phosphorylation*

After equilibration, arterioles were exposed to one of several intraluminal pressure levels (30, 70, 120 or 150 mmHg). To ensure steady-state, vessels were maintained at their collection pressure for a minimum of 15 minutes before freezing. In addition to collecting samples in the active state, arterioles were also studied in the passive state as described above. Prior to collection of samples internal diameter measurements were taken for calculations of wall tension.

### *Effect of ML-7 on Arteriolar Tone*

To provide additional evidence for the involvement of MLC phosphorylation in setting of basal tone and myogenic reactivity, studies were performed in the presence and absence of the myosin light chain kinase inhibitor ML-7 (1-[5-iodonaphthalene-1-sulfonyl]-1H-hexahydro-1,4-diazepine hydrochloride) (Biomol, Plymouth, PA). In the control condition (0 mM ML-7) arteriolar diameter and intracellular  $\text{Ca}^{2+}$  were collected at 30, 50, 70, 100 and 120 mmHg after which the vessel was continually superfused with either 3 or 10  $\mu\text{M}$  ML-7. This agent has been reported to possess relative specificity for myosin light chain kinase and has typically been used over the concentration range employed in the present study (Nishikawa, et al., 1985; Ratz, 1993). After a 15 minutes period the  $\text{Ca}^{2+}$  and diameter measurements were repeated. Control experiments were studied to examine the effects of time and repeated pressure steps.

### *Drugs and Chemicals:*

Unless stated all chemicals were obtained from Sigma Chemical Company (St. Louis, MO). ML-7 was prepared as a stock solution ( $10^{-2}\text{M}$ ) in ethanol with subsequent dilutions in buffer as required.

### Results

Consistent with previous studies (Hill and Meininger, 1994; Meininger, et al., 1991), in the presence of extracellular  $\text{Ca}^{2+}$ , isolated cremaster muscle arterioles exhibited pressure-dependent myogenic vasoconstriction over an approximate pressure range of 30 - 150 mmHg (Figure 4-1A). In the absence of  $\text{Ca}^{2+}$ , vessels responded passively to

increases in intraluminal pressure (Figure 4-1A). Relative to the passive state, active pressure-dependent vasoconstriction resulted in near maintenance of a constant wall tension despite increased intraluminal pressure (Figure 4-1B).

*Effect of Steady-State Intraluminal Pressure on Arteriolar Wall  $\text{Ca}^{2+}$*

Steady-state  $[\text{Ca}^{2+}]_i$ , as measured by the 340/380 nm fluorescence ratio, was found to increase with increasing intraluminal pressure (Figure 4-2A). Regression analysis indicated that the relationship between pressure and intracellular  $\text{Ca}^{2+}$  approximated a linear function ( $\%R_{340/380}$  at 30 mmHg =  $0.32 \times \text{pressure} + 91.15$  ;  $r^2 = 0.60$ ,  $p < 0.001$ ). Over the pressure range studied estimated  $[\text{Ca}^{2+}]_i$  varied from  $91.4 \pm 10.9$  nM at 30 mmHg to  $201.4 \pm 27.5$  nM at 150 mmHg (Fig 4-2B). In contrast to data obtained in the active state (2.5 mM  $\text{Ca}^{2+}$  superfusate), no significant pressure-induced changes in fluorescence were detected after vessels were made passive by superfusion with buffer containing 0 mM  $\text{Ca}^{2+}$ /2 mM EGTA (Figure 4-2A). For example, in the passive state estimated  $[\text{Ca}^{2+}]_i$  was  $37.2 \pm 6.4$  nM and  $35.5 \pm 9.0$  nM at 30 and 150 mmHg (Fig. 4-2B).

Over the pressure range 30 - 120 mmHg, a significant linear correlation ( $\%R_{340/380}$  at 30mmHg =  $0.07 \times \text{wall tension} + 87.30$  ;  $r^2 = 0.72$ ,  $p < 0.001$ ) was obtained between intracellular  $\text{Ca}^{2+}$  and wall tension (Figure 4-2C).

*Effect of Steady-State Intraluminal Pressure on Myosin Light Chain Phosphorylation*

The extent of phosphorylation of the 20 kD regulatory MLC (at steady-state) was found to increase with increased intraluminal pressure (Figure 4-3). Thus, MLC phosphorylation at a pressure of 70 mmHg was  $26.7 \pm 2.3$  % while significantly ( $p < 0.001$ ) increasing to  $39.6 \pm 3.0\%$  at a pressure of 120 mmHg. In the absence of

Figure 4-1. Relationship between arteriolar diameter, pressure and wall tension. The upper panel (A) shows the pressure-diameter relationships for cremaster muscle first order arterioles, obtained under active (2.5 mM extracellular  $\text{Ca}^{2+}$ ) and passive (0 mM  $\text{Ca}^{2+}$ /2mM EGTA superfusate) conditions. The lower panel (B) illustrates the relationship between calculated wall tension (pressure x radius; dynes/cm) and intraluminal pressure for the data shown in the upper panel. The data presented in panel B were directly derived from that in panel A and as such error bars have been omitted. Results are presented as mean  $\pm$  SEM.

**A.****B.**

**Figure 4-2. Relationship between arteriolar  $[Ca^{2+}]_i$ , pressure and wall tension. The upper figure (A) illustrates the effect of intraluminal pressure on  $[Ca^{2+}]_i$  levels expressed as the 340/380nm fluorescent ratio ( $R_{340/380}$ ); data is shown for the active and passive states. The middle panel (B) shows the estimated  $[Ca^{2+}]_i$  (nM) over the pressure range 30 - 170 mmHg. The lower figure (C) shows the relationship between calculated wall tension and  $[Ca^{2+}]_i$ . As described in the text a significant ( $r^2 = 0.72$  ,  $p < 0.001$ ) linear correlation was obtained between tension and  $[Ca^{2+}]_i$ .**

extracellular  $\text{Ca}^{2+}$  MLC phosphorylation was low and did not vary with pressure. As such, data obtained in the passive state was combined, resulting in a phosphorylation level of  $8.5 \pm 0.7 \%$  ( $n = 7$ ).

No measurable difference in the extent of phosphorylation was detected between intraluminal pressures of 30 and 70 mmHg (27.7 and 26.7 %, respectively). This could not be entirely explained by insensitivity of the electrophoretic approach, as consistently lower phosphorylation levels were obtained for the unstimulated aortic control tissues ( $14.5 \pm 0.8 \%$ ) and samples of arterioles collected in the passive state ( $8.5 \pm 0.7 \%$ ). No significant correlation was evident between arteriolar diameter (mean active diameter for each pooled sample) and the extent of MLC phosphorylation (Figure 4-4A); however when phosphorylation was considered in terms of wall tension (pressure  $\times$  radius) a significant relationship was apparent (Figure 4-4B). Linear regression analysis of the tension (dynes/cm)/phosphorylation (% total) data resulted in a slope value of 0.026 and Y intercept of 18.35 ( $r^2 = 0.61$ ,  $n = 23$ ) with the slope being significantly ( $p < 0.001$ ) different from zero.

#### *Effect of ML-7 on Arteriolar Tone*

The myosin light chain kinase inhibitor ML-7 had little effect on pressure-induced changes in intracellular  $\text{Ca}^{2+}$  (Figure 4-5A). The small inhibitory effect evident at higher pressures (100 and 120mmHg) appears to be explained by time-dependent effects as a similar response was noted in vessels subjected to three sequences of pressure steps ( $n=3$ , data not shown). Importantly, despite the presence of the higher concentrations of the inhibitor (10  $\mu\text{M}$ ), increases in  $\text{Ca}^{2+}$ , as assessed by both changes in the 340/380 ratio and

Figure 4-3. Level of myosin light chain phosphorylation expressed as a percentage of total myosin light chain. To the left of the figure results are shown for the level of phosphorylation in cremaster arterioles exposed to 0mM Ca<sup>2+</sup>/2mM EGTA and the pooled aorta sample which was used as a control (see text). To the right of the figure data are shown to indicate the effect of intraluminal pressure on myosin light chain phosphorylation under active conditions. Results are expressed as mean  $\pm$  SEM. \*  $p < 0.001$  vs. 0 mM Ca<sup>2+</sup>; #  $p < 0.01$  vs. 30 mmHg.

Figure 4-4. Relationship between myosin light chain phosphorylation and diameter (A) or calculated wall tension (B). A significant linear correlation ( $r^2 = 0.61$ ,  $p < 0.001$ ) was obtained between tension and phosphorylation while the relationship between phosphorylation and diameter was not statistically significant ( $r^2 = -0.05$ ,  $p = 0.319$ ).

**A.****B.**

Figure 4-5. Effect of the myosin light chain kinase inhibitor, ML-7, on pressure-induced changes in  $[Ca^{2+}]_i$  (A) and diameter (B).  $Ca^{2+}$  data are presented as percent of  $[Ca^{2+}]_i$  (nM) at 30 mmHg and diameter as percent diameter at 30mmHg. Results are expressed as mean  $\pm$  SEM. \*  $p < 0.05$  compared to control condition.

**A.****B.**

calculated  $\text{Ca}^{2+}$  levels, followed each pressure step. In contrast to the effect on  $\text{Ca}^{2+}$ , ML-7 caused dose-dependent inhibition of the diameter response to alterations in intravascular pressure (Figure 4-5B). At the highest ML-7 concentration examined (10 $\mu\text{M}$ ) the response of arterioles to increases in intraluminal pressure paralleled that obtained in the passive state (0 mM  $\text{Ca}^{2+}$ /2mM EGTA), despite divergent  $\text{Ca}^{2+}$  responses (Figure 4-5B).

To confirm that ML-7 inhibited MLC phosphorylation, arterioles, at a steady-state intraluminal pressure of 120 mmHg, were exposed to 10 $\mu\text{M}$  ML-7 for 15 minutes and collected for gel electrophoresis. The level of 20 kD MLC phosphorylation was reduced to 21.9% (n=2) compared with 39.6% in the absence of ML-7.

### Discussion

The results of this study demonstrate that arteriolar myogenic constriction is associated with elevation of intracellular  $\text{Ca}^{2+}$  and an increased level of MLC phosphorylation. Further, data obtained in the presence of the myosin light chain kinase inhibitor ML-7 suggest that an increase in the extent of phosphorylation of the myosin regulatory light chains, but not an increase in  $[\text{Ca}^{2+}]_i$  alone, is required for development and maintenance of spontaneous basal tone. That is, in the presence of the MLCK inhibitor, arterioles failed to constrict despite pressure-induced increases in intracellular  $\text{Ca}^{2+}$ .

The results of the present study, to the best of our knowledge, represent the first report of MLC phosphorylation in true resistance vessels. Previously it has been assumed that data obtained using segments of agonist-exposed conduit vessels are applicable to

events occurring in arterioles (Meininger and Davis, 1992). In an attempt to establish relationships between arterial resistance and phosphorylation, Moreland et al. (1984), using an *in situ* preparation of the canine anterior tibial artery, demonstrated that phenylephrine-induced increases in arterial resistance were associated with increased levels of MLC phosphorylation. Although not specifically examined in their study, this preparation would not be expected to possess significant spontaneous basal tone. Consistent with this suggestion, Moreland et al. (1984) reported a low level of *in vivo* basal phosphorylation ( $13 \pm 2 \%$ ) which is comparable to *in vitro* unstimulated levels in conduit arteries and the aorta control sample used in the present study ( $14.5 \pm 0.8 \%$ ). More recently, Laporte et al. (1994) reported MLC phosphorylation levels associated with stretch-induced tone *in vitro* ring segments of the rabbit facial vein. These authors found stretch-induced myogenic tone to be associated with increased  $\text{Ca}^{2+}$  influx and MLC phosphorylation compared to the unstretched state, however, the response to graded stretch was not determined. Similarly, Ledvora et al. (1983) demonstrated stretch-induced MLC phosphorylation in isolated segments of carotid artery. While these studies can be used to suggest a role for myosin phosphorylation in pressure/stretch phenomena they were not able to establish the relationships among intraluminal pressure,  $[\text{Ca}^{2+}]_i$ , phosphorylation and extent of contraction.

Of interest was the observed correlation between calculated wall tension (pressure x radius) and both intracellular  $\text{Ca}^{2+}$  and the extent of MLC phosphorylation. Although indirect, these findings are consistent with the hypothesis that wall tension (or a related variable) is the membrane signal which initiates myogenic constriction and therefore

perhaps the controlled variable in myogenic responsiveness (Johnson, 1980). Despite tension being linearly correlated with  $\text{Ca}^{2+}$  and phosphorylation, total wall tension was found to be most closely regulated over an approximate physiologic pressure range (40 - 120 mmHg). This presumably is indicative that other factors, such as a tendency towards a degree of passive collapse at low distending pressures and a relative inability to contract against high distention pressure, limits the effectiveness of the control mechanism.

If wall tension is a sensed and controlled variable then an important question is, what maintains the increased levels of  $[\text{Ca}^{2+}]_i$  and phosphorylation in the steady state condition - that is after pressure-induced myogenic vasoconstriction has occurred and wall tension has stabilized toward baseline? This suggests that the arteriole has shifted to a state of higher activation; a response necessary to maintain a near stable wall tension in the face of increased intraluminal pressure. Under this condition, if steady-state intracellular  $\text{Ca}^{2+}$  (and hence myosin light chain kinase activity) were to decrease, vessel distention would occur with a subsequent increase in wall tension.

Figure 4-6 shows the calculated vessel diameter at different pressures based on an ideal wall tension (vessel diameter =  $0.5 \times \text{wall tension}/\text{pressure}$ ) regulation, assuming the wall tension at 70mmHg is the controlled value. We can see that the measured diameters come very close to the calculated values within a range of 30-120 mmHg, which correlates approximately to the physiological blood pressure range for arterioles. This finding possesses significance in two ways: it supports the idea that wall tension be the controlled variable for arteriolar myogenic reactivity and gives a clear view for the role of myogenic vasoregulation on local blood flow.

Figure 4-6. Calculated vessel diameter based on the idea that wall tension is the controlled parameter for arteriolar myogenic reactivity and do not change with pressure. Wall tension at 70mmHg is considered to be the controlled value here.

The results of the present study may be of direct relevance to previous reports of modulation of arteriolar agonist responsiveness by intraluminal pressure (Harder, 1988; Nilsson, and Sjoelholm, 1985; VanBavel and Mulvany, 1994). As pressure is increased so is the level of  $[Ca^{2+}]_i$  and MLC phosphorylation, which would be expected to place the vessel in a more activated state or on a steeper section of the  $Ca^{2+}$  (or phosphorylation)-contraction relationship. This being the case, agonist responsiveness may vary with intraluminal pressure in a manner determined by the effect of pressure/wall tension on the level of  $[Ca^{2+}]_i$  and MLC phosphorylation. Further studies are required to examine the interrelationships among intravascular pressure,  $[Ca^{2+}]_i$  and myosin phosphorylation in arterioles exposed to contractile agents.

In recent years several studies including our own have been used to support a role for protein kinase C in modulating basal tone and myogenic reactivity (Hill, et al., 1990; Laher and Bevan, 1987; Osol, et al., 1991). For example, the protein kinase inhibitors staurosporine and H7 were found to inhibit myogenic responsiveness of small cremaster muscle arterioles while the protein kinase C activator, (-)-indolactam potentiated myogenic vasoconstriction. Support for a possible role of protein kinase C is also provided by the observation that increased intraluminal pressure/wall tension results in increased production of DAG (Narayanan, 1994), the physiological activator of protein kinase C. These earlier studies, however, do not necessarily exclude an underlying contribution of the MLC phosphorylation pathway. Indeed at the inhibitor concentrations used basal tone was not inhibited despite marked attenuation of the constrictor response to an acute increase in intravascular pressure. In addition, studies in our laboratory have

shown, in mesenteric resistance vessels, that protein kinase C-mediated contractions are dependent on a basal level of  $[Ca^{2+}]_i$  and are inhibited by the myosin light chain kinase inhibitor, ML-9 (Hill, et al., 1995). As such, a contribution from multiple mechanisms may occur; however, activation of the myosin light chain kinase pathway appears obligatory.

In regard to methodological considerations the two dimensional gel electrophoretic approach used in these studies detects phosphorylation of myosin light chain by the shift in isoelectric point [the PI for phosphorylated and unphosphorylated MLC are approximately 4.97 and 5.05, respectively (Silver and Stull, 1981)]. As such, this method may not be expected to distinguish between single phosphorylations occurring at different sites. For example, MLCK results in MLC phosphorylation at serine 19 while protein kinase C causes phosphorylation at serine 1 and 2 (Murphy, 1994; Somlyo and Somlyo, 1994). However, as exposure of arterioles to the MLCK inhibitor, ML-7, resulted in an apparent dissociation between  $[Ca^{2+}]_i$  levels and arteriolar diameter it appears evident that arteriolar tone and myogenic reactivity are dependent on MLCK-mediated phosphorylation. This is further supported by the observation that, in addition to inhibiting myogenic tone, ML-7 inhibited the pressure-dependent increase in MLC phosphorylation as shown by gel electrophoresis. An additional argument against the involvement of MLC phosphorylation at sites other than serine 19 is provided by *in vitro* studies demonstrating that protein kinase C-induced phosphorylation at sites serine 1 and 2 results in inhibition of smooth muscle contraction rather than activation (Parente, et al., 1992; Saitoh, et al., 1987). It would therefore be inconsistent that increased myogenic tone would be associated with

increased phosphorylation at such sites. Definitive evidence for MLC serine 19 phosphorylation during myogenic vasoconstriction would require an approach such as  $^{32}\text{P}$ -ATP labeling followed by tryptic phosphopeptide mapping. While this would be exceptionally difficult to perform on microvascular preparations it is important to note that stretch activation of carotid artery strips has been shown to be associated with [ $^{32}\text{P}$ ] incorporation into MLCK phosphorylated peptides (Barany, et al., 1990). Collectively the above evidence strongly supports the methodological approach used and the proposition that basal arteriolar tone and myogenic reactivity is dependent on MLCK mediated phosphorylation of the myosin regulatory light chain.

In summary, the results of the present study demonstrate that the setting of basal arteriolar tone and myogenic reactivity is dependent on the classical  $\text{Ca}^{2+}$ -stimulated MLC phosphorylation pathway of smooth muscle contraction. Further, the data suggest that in the steady-state the effect of an intraluminal pressure increase may be detected by alterations in wall tension or a related variable.

## **CHAPTER V**

### **ROLE OF $Ca^{2+}_i$ AND MYOSIN PHOSPHORYLATION IN MYOGENIC AND AGONIST-INDUCED ARTERIOLAR CONTRACTIONS**

Arterioles characteristically display three types of contractions: 1) basal tone - a maintained state of partial constriction; 2) myogenic contraction - constriction in response to an acute increase in vascular pressure; and 3) reactivity to circulating hormones and neurotransmitters such as norepinephrine. Arteriolar basal tone and myogenic contraction are related and sometimes addressed together as myogenic reactivity, however, the underlying cellular mechanisms may not exactly be the same (Meininger and Davis, 1992). In particular, the cellular events occurring in response to the distention phase of an acute increase in pressure may be obscured by the time steady-state myogenic constriction is achieved.

Agonist-induced smooth muscle contraction has been suggested to consist of two phases, the initial force developing phase and the following phase of sustained contraction (Aksoy, et al., 1986; Moreland, et al., 1990). MLC phosphorylation is believed to be a prerequisite for the initial tension development or contraction. While MLC phosphorylation is decreased during the second phase of contraction, the explanation for the maintained tension has been controversial. Evidence exists for both the "latch bridge" model (Hai and Murphy, 1988) and the hypothesis of thin filament regulation (for review

see Walsh, 1994). Moreover, PKC mediated contractile apparatus sensitization for  $\text{Ca}^{2+}$  has been reported following agonist stimulations (Nishimura, et al., 1990; Itoh, et al., 1993). Such studies, however, are limited to smooth muscle from conduit vessels or non-vascular tissues.

The setting of arteriolar basal tone has been demonstrated to be dependent on  $\text{Ca}^{2+}$ /CaM activated MLC phosphorylation (Chapter 4). However, whether this holds true for an acute myogenic contraction and arteriolar responsiveness to agonists, such as  $\alpha$ -adrenergic agents, has not been determined. Similarly it is unknown whether microvascular smooth muscle shows dissociation between force production (i.e. vasoconstriction) and  $[\text{Ca}^{2+}]_i$ /MLC phosphorylation during the maintained phase of myogenic or agonist activation. Therefore, to elucidate temporal aspects of  $\text{Ca}^{2+}$ /MLC signaling, the aims of this study were to test the hypotheses that 1) the arteriolar contractions following acute pressure increases and agonist stimulation also depend on  $[\text{Ca}^{2+}]_i$  and MLC phosphorylation; and 2) the temporal relationships between stimulus and response are different when comparing pressure- and agonist-stimulation, reflecting difference in signal transduction and  $\text{Ca}^{2+}$  handling.

#### Methods and Experimental Protocols

Vessel cannulation,  $[\text{Ca}^{2+}]_i$  measurement and MLC sample preparation were performed as described in chapter 2. Briefly, isolated rat cremaster first order arterioles were cannulated in a superfusion chamber and initially set at a transmural pressure of 70mmHg in the absence of intraluminal flow. Vessels were superfused with Krebs buffer

and maintained at 34°C throughout each of the experiments.  $[Ca^{2+}]_i$  was measured using fura-2 as a fluorescent indicator and fluorescence ratio  $R_{340/380nm}$  was used for measurement of changes in  $[Ca^{2+}]_i$ . MLC isoforms were separated by two dimensional polyacrylamide gel electrophoresis. To ensure adequate loading of protein from the microvessel segments it was necessary to pool samples. The separated proteins were quantitated using a computerized image analysis system and MLC phosphorylation expressed as percent phosphorylated MLC of total 20kD MLC. As an index of reproducibility between electrophoretic separations a standard sample of homogenized rat aorta (obtained under conditions of 0 mmHg transmural pressure while superfused with a buffer containing 2.5mM  $Ca^{2+}$ ) was processed on each day; the extent of phosphorylation was determined to be  $14.9 \pm 0.5\%$  (mean  $\pm$  SEM),  $n = 12$  determinations.

#### *Time Course of $Ca^{2+}$ Measurements*

The following general time course for  $[Ca^{2+}]_i$  measurements was used for both pressure and agonist-stimulations: immediately prior to the increase of pressure or application of NE, six (6) pairs of fluorescence images from 340nm and 380nm excitation were collected at 10 second intervals. Following the stimulation, twelve (12) image pairs were collected at 2 second intervals, then four (4) pairs were taken at 10 second intervals followed by eight (8) pairs at 30 second intervals. A total of thirty (30) pairs of images were taken for each stimulation which covered a 5 minute period post stimulation. For extended monitoring, such as following some of the larger pressure steps, measurements were taken at 30 second or 120 second intervals after the initial 5 minute period.

### *Sample Collection for MLC Phosphorylation*

To avoid time delay and diffusion errors during NE stimulation, applications of the agonist were carried out by a complete bath change when preparing samples for MLC phosphorylation. With the superfusion pump stopped, buffer in the cannulating chamber was rapidly drained with an electric vacuum and quickly replaced with pre-warmed buffer containing an appropriate concentration of NE. The enzymatic reactions were promptly stopped by freezing the vessel segment with acetone/dry ice at the desired time points (~4 seconds, 10~15 seconds and 5 minutes) after the stimulation (application of NE, or pressure step).

The whole procedure was video taped for quick collections (< 15 seconds) and an electronic time generator was used to post time stamps on the tape which allows the confirmation of reaction time before freezing upon replay. For collection of samples at 5 minutes, an electronic caliper coupled to a chart recorder was used for monitoring vessel diameter changes.

### Results

#### *Arteriolar diameter and $Ca^{2+}$ response to acute increase in intraluminal pressure*

To determine the time necessary to ensure that steady-state arteriolar diameter and intracellular  $Ca^{2+}$  levels had been achieved, following an acute increase in intravascular pressure, the response to a pressure change from 70 - 100 mmHg was followed in a time-dependent fashion (Figure 5-1). The acute pressure step resulted in an initial arteriolar

Figure 5-1. Arteriolar diameter and  $\text{Ca}^{2+}$  responses to an increase in intraluminal pressure from 70 to 100 mmHg. Absolute arteriolar diameter at 70 mmHg was  $85.6 \pm 5.8 \mu\text{m}$ . Data are normalized to account for differences in control diameter and  $[\text{Ca}^{2+}]_i$  values, respectively. Panel A illustrates that the acute pressure step results in an initial distention of the arterioles followed by vasoconstriction to a diameter significantly smaller than control diameter.  $[\text{Ca}^{2+}]_i$  (panels B) is seen to increase as the arteriole is distended. Steady-state diameter and  $\text{Ca}^{2+}$  values are obtained within a 5 minute period. Results are presented as mean  $\pm$  SEM; \* indicates significant different from basal,  $p < 0.05$ .

**A.****B.**

distention followed by vasoconstriction to a diameter significantly ( $p < 0.05$ ) smaller than the control diameter. Intracellular  $\text{Ca}^{2+}$  showed a monophasic response to the 30 mmHg pressure step, increasing as the vessel was distended and remaining elevated for the duration of the pressure increase. Stable arteriolar diameters and intracellular  $\text{Ca}^{2+}$  levels were reached within a five minute period.

Similar responses were seen when the same size pressure step increase (30mmHg) was applied to the vessels from different starting (baseline) pressures (Figure 5-2). Vessels have less tone at 30mmHg compared with vessels at 120mmHg, and hence the same stimulus stretches the vessels out further ( $109.6 \pm 0.9\%$  compared with  $101.9 \pm 0.5\%$ ,  $n = 10$  and  $9$ , respectively;  $p < 0.001$ ). A greater  $\text{Ca}^{2+}$  rise was seen to the pressure increase of 30 to 60mmHg ( $120.0 \pm 2.6\%$  compared with  $110.0 \pm 1.3\%$  corresponding to pressure increasing from 120 to 150mmHg). If the response to 70-100mmHg is plotted, it falls in between the curves for 30 to 60mmHg and 120 to 150mmHg and located somewhat closer to the latter one. A comparison of vessel responses to 30 to 60mmHg vs. 120 to 150mmHg is summarized in Table 5-1. Arteriolar diameter and  $\text{Ca}^{2+}$  responses were also examined when vessels were subjected to greater stretches - pressure step-increased from 50 to 120mmHg and from 30 to 150mmHg (Figures 5-3 and 5-4, respectively). The vessels were forced out further to  $112.5 \pm 1.5\%$  and  $124.3 \pm 2.9\%$  of basal diameters, respectively, and the corresponding maximum  $\text{Ca}^{2+}$  increase were  $129.8 \pm 4.1\%$  and  $201.6 \pm 12.0\%$ . The responses to 30-150mmHg were monitored for a longer period of time, 30 minutes after the pressure step, because it was apparent that

Figure 5-2. Arteriolar diameter (A) and  $\text{Ca}^{2+}$  (B) responses to pressure step increases from 30mmHg to 60mmHg and 120mmHg to 150mmHg. Data are presented as mean  $\pm$  SEM and normalized to the basal conditions.

**A.****B.**

Table 5-1. Comparison of arteriolar responses to 30mm Hg pressure increase starting at 30 and 120mm Hg.

	Diameter	Tension	peak [Ca <sup>2+</sup> ] <sub>i</sub>	steady state [Ca <sup>2+</sup> ] <sub>i</sub>	contraction
30-60mmHg	110%	219%	120%	111%#	93.6%
120-150mmHg	102%*	128%*	110%*	104%*#	96.4%*

All data are presented as changes normalized to the basal conditions (before the pressure step). \* indicates significantly different from the corresponding response starting at 30mmHg; # indicates significantly different from peak value of the same pressure step;  $p < 0.05$ .

despite the large increase in  $[Ca^{2+}]_i$ ; it takes a much longer time period for the vessels to contract following such an extensive stretch.

Linear regressions were fitted between maximum distention (% basal diameter), maximum wall tension increase (% basal wall tension) and maximum  $Ca^{2+}$  increase (% basal  $[Ca^{2+}]_i$ ) of the vessels (Figure 5-5). Wall tension was calculated using the Laplace relationship (pressure x radius), here the radius value was taken from the pixel measurement from a region covering vessel diameter in the fluorescent ratio image. Points in the diagrams represent each individual vessel from all of the pressure steps (n=50). A slightly better linear correlation was obtained in the relationship between tension increase and  $[Ca^{2+}]_i$  increase ( $y = 0.23x + 72.9$ ,  $p < 0.001$ ,  $r^2 = 0.83$ ) than between stretch and  $[Ca^{2+}]_i$  increase ( $y = 4.07x - 313.5$ ,  $p < 0.001$ ,  $r^2 = 0.72$ ), which further suggests the role of wall tension in regulating myogenic reactivity.

#### *MLC phosphorylation levels following an acute pressure step*

MLC phosphorylation levels were examined following a 70-100mmHg pressure increase. From a basal level of  $26.7 \pm 2.3\%$  (n=6), MLC phosphorylation increased to  $37.0 \pm 2.1\%$  ( $p < 0.05$ , n=6) in 10 to 15 seconds after the pressure step while decreasing to  $31.9 \pm 1.1\%$  (n=5) at 5 minutes. Corresponding to 10-15 seconds after pressure increase from 70 to 100mmHg is the time when  $[Ca^{2+}]_i$  reaches the maximum level and the vessels start to contract (refer to Figure 5-1).

Figure 5-3. Arteriolar diameter (A) and  $\text{Ca}^{2+}$  (B) responses to pressure step increase from 50mmHg to 120mmHg and followed by return to 50mmHg. The vessels were monitored for 10 minutes after each pressure change to ensure the steady state had been reached. By relaxing the vessels, the arteriolar myogenic reactivity also exhibited its function following pressure reduction. Data are presented as mean  $\pm$  SEM and normalized to the basal conditions (n=5).

**A.****B.**

Figure 5-4. Arteriolar diameter (A) and  $\text{Ca}^{2+}$  (B) responses to an acute 30-150mmHg pressure step.  $[\text{Ca}^{2+}]_i$  showed a biphasic increase, however, this was exaggerated by extending the monitoring time to 30 minutes. No significant contraction or  $[\text{Ca}^{2+}]_i$  decrease was observed at 5 minute, which is the time period usually used for monitoring a arteriolar response. Data are presented as mean  $\pm$  SEM and normalized to the basal conditions(n=5).

**A.****B.**

**Figure 5-5. Relationship between pressure step-induced stretch and  $[Ca^{2+}]_i$  increases (A), and increase in wall tension and  $[Ca^{2+}]_i$  increase (B). Data came from all the pressure step experiments, n=50.**

### *Arteriolar diameter and $\text{Ca}^{2+}$ response to agonist stimulation*

Arteriolar diameter and  $\text{Ca}^{2+}$  responses to the  $\alpha$ -adrenergic agonist, NE, were also examined. Vessels constricted rapidly to NE, 0.1, 1 and 5  $\mu\text{M}$ , in a dose dependent manner and the contractions were maintained in presence of agonist (Figure 5-6A). For instance, in response to 0.1, 1 and 5  $\mu\text{M}$  NE, the vessels maximally constricted to  $89.2 \pm 2.3 \%$ ,  $77.4 \pm 1.6 \%$  and  $76.0 \pm 1.5 \%$  of the basal diameter, respectively. However,  $[\text{Ca}^{2+}]_i$  showed more biphasic responses with a rapid spike followed by a plateau phase which remained a significantly increased level at higher concentrations of agonist (Figure 5-6B). The magnitude of both the peak values and the maintained levels at steady states were NE dose dependent. For example, the peak values of  $[\text{Ca}^{2+}]_i$  increase are  $120.5 \pm 3.7 \%$ ,  $191.3 \pm 11\%$ , and  $257.0 \pm 21.0 \%$  corresponding to 0.1, 1, and 5  $\mu\text{M}$  NE stimulation.

### *MLC phosphorylation levels following an agonist stimulation*

MLC phosphorylation levels following 5  $\mu\text{M}$  NE stimulation were measured (Figure 5-7). Corresponding with the rapid increase in  $[\text{Ca}^{2+}]_i$  and vessel contraction, MLC phosphorylation increased to a level of  $48.3 \pm 2.1\%$  ( $n=6$ ) within 3~5 second of agonist stimulation. This level decreased to  $36.6 \pm 2.5 \%$  ( $n=5$ ) in 10~15 seconds and maintained at  $34.1 \pm 2.1\%$  ( $n=5$ ) at 5 minutes. 3~5 seconds approximates the time when  $[\text{Ca}^{2+}]_i$  reaches the peak level. The MLC phosphorylation levels remained significantly increased during the entire agonist stimulation period.

### *Comparison of myogenic and agonist-induced contractions*

A comparison of arteriolar myogenic constriction (50-120mmHg pressure step) and a comparable contraction to agonist (0.1  $\mu\text{M}$  NE) is shown in figure 5-8. In response to the

**Figure 5-6. Arteriolar diameter (A) and  $\text{Ca}^{2+}$  (B) responses to 0.1 $\mu\text{M}$ , 1 $\mu\text{M}$ , and 5 $\mu\text{M}$  NE stimulations. Data are normalized to the basal conditions.**

Figure 5-7. MLC phosphorylation following NE stimulation. Data are presented as mean  $\pm$  SEM. \* indicates significant different from basal, # indicated significant from maximum;  $p < 0.05$ .

Figure 5-8. Comparison of arteriolar diameter (A) and  $\text{Ca}^{2+}$  (B) responses to an acute pressure increase and a comparable NE stimulation. Data are presented as mean  $\pm$  SEM and normalized to the basal conditions. \* indicates significant different from basal,  $p < 0.05$ .

**A.****B.**

acute pressure increase, vessels ( $n = 9$ ) were first distended then slowly contracted to and maintained at smaller diameter while the agonist caused a rapid constriction (at 50 mmHg,  $n = 8$ ). Although the vessels from both groups constricted to about the same level at steady states ( $94.9 \pm 1.9\%$  and  $94.1 \pm 2.1\%$  of basal, respectively), the patterns of contraction were completely different. Further,  $\text{Ca}^{2+}$  responses were also distinct, for example, at the end of the 5 minute stimulation,  $[\text{Ca}^{2+}]_i$  remained significantly elevated in the pressure increased vessels ( $118.7 \pm 1.6\%$ ,  $p < 0.01$ ) while declining towards the base line level in agonist-challenged vessels ( $99.3 \pm 4.2\%$ ).

### Discussion

The results from this study demonstrate that both arteriolar myogenic and agonist induced contractions are associated with increases in  $[\text{Ca}^{2+}]_i$  and myosin phosphorylation. Further, the increase in vessel wall tension following an acute pressure step correlates linearly ( $r^2 = 0.83$ ) to the resultant peak increase in  $[\text{Ca}^{2+}]_i$ . Higher concentrations of agonist, as well as larger steps of pressure increase, induced  $\text{Ca}^{2+}$  response shows two phases: a transient rapid increase followed by a sustained elevation. Agonist could constrict arterioles to a similar extent as myogenic contraction but at much lower  $[\text{Ca}^{2+}]_i$ , suggesting that the arteriolar contractile apparatus is more sensitive to  $\text{Ca}^{2+}$  during agonist induced contraction than during pressure-induced contraction and implying the possible involvement of additional regulatory mechanisms.

It is currently generally accepted that smooth muscle contraction is caused by  $\text{Ca}^{2+}$ /CaM activated MLC phosphorylation by MLCK. However, this mechanism has not been

tested in resistance vessels probably because of the technical difficulties involved in and the enormous time and patience required for the subject. As far as we know, this study is the first to demonstrate the levels of MLC phosphorylation in arteriolar contraction occurring in response to either pressure or agonist stimulations. Our knowledge on smooth muscle contractions has, thus far, come largely from studies performed on large vessels or non-vascular smooth muscles. Several studies have demonstrated that physical stretch of smooth muscles will cause an increase in  $[Ca^{2+}]_i$ ; and this has been confirmed both at single cell level (Davis, Meininger and Zawieja, 1992; Wellner and Isenberg, 1994) and in smooth muscle tissues from different vascular sites (Laher and Bevan, 1989; Meininger, et al., 1990). There are also reports to show that stretch of both vascular and non-vascular smooth muscles can activate MLCK and increase MLC phosphorylation (Barany, et al., 1990; Csabina, et al., 1986; Ledvora, et al., 1983). However, the experimental approaches involved in these studies may not be physiological. For example, in the studies of Barany et al. and Ledvora et al., MLC phosphorylation levels were measured when porcine carotid arterial smooth muscle strips were stretch to 1.7 times their resting lengths which would not be expected to occur in a *in vivo* situation. Although the MLC phosphorylation levels from the studies of Csabina et al. were found to be increased upon stretch and decayed with time,  $[Ca^{2+}]_i$  was not monitored in their study and therefore, the correlation between  $[Ca^{2+}]_i$  and MLC phosphorylation was not provided. Experimental methodologies employed in the present study, i.e. changing of intraluminal pressure within a physiological range in cannulated arterioles which demonstrate spontaneous tone, enables us to provide results of close physiological relevance. The dependency of arteriolar myogenic and agonist-induced contraction on  $Ca^{2+}$ ; and MLC

phosphorylation, as demonstrated in the present study, further confirmed their obligatory roles in smooth muscle contraction, in general.

Decreases in MLC phosphorylation during the prolonged, sustained phase of arteriolar contractions to pressure increases and agonist stimulation were observed in the present study. The decrease in MLC phosphorylation was accompanied by a decline in  $[Ca^{2+}]_i$ , for example, the  $[Ca^{2+}]_i$  increase at 5 minutes after  $5\mu M$  NE stimulation was  $127.1 \pm 5.4\%$  compared with  $257.0 \pm 21.0\%$  at the maximum increase during the earlier phase. This phenomenon is consistent with the reported observations from other studies (Csabina, et al., 1986; Moreland, et al., 1992). In the studies of Csabina et al., they found that stretch-induced MLC phosphorylation of rat uterus smooth muscle decreased from a maximum value of 83% (within 1 minute of stimulation) to 22% in 30 minutes. It can possibly be explained by the 'latch-bridge' hypothesis put forward by Hai and Murphy (1988) that the actomyosin interaction has changed from a state of active cross-bridge cycling to a state of dephosphorylated, non-cycling attachment of myosin heads to actin filaments. In the case of cannulated arterioles this may translate to the tendency for the vessel to hold its diameter rather than further constricting. The transient increase in MLC phosphorylation observed by Moreland et al. (1992) was under a  $Ca^{2+}$  clamped condition may suggest a novel regulatory mechanism. However, this may or may not be involved in our studies because the increase in MLC phosphorylation was accompanied by an increase in  $[Ca^{2+}]_i$ . Thin filament regulation is a possible alternative explanation to this situation. It is also possible that caldesmon or calponin, as suggested by other investigators (Katryama, et al., 1992; Walsh, 1994), come in to play during this latter phase, however, studies of thin filament regulation in intact vessels are lacking. Further

biochemical studies will be needed to address the involvement of these possibilities in arteriolar smooth muscle contraction.

From the previous chapter, we know that steady state  $[Ca^{2+}]_i$  at 120mmHg is significantly higher than that at 30mmHg, and this increased  $[Ca^{2+}]_i$  may indicate a more activated state of the vessel at higher pressures. Therefore, comparison of the vessels' response to the same pressure/stretch stimulation (i.e. 30mmHg pressure step) at different starting pressure will allow us to examine the modulatory effect of varied levels of basal activation. While 70mmHg is considered the *in vivo* pressure for rat cremaster first order arterioles, 30mmHg and 120mmHg corresponds to the two pressures within which the myogenic regulation appears to be most effective (refer to Figure 4-1). Vessels were found to be distended further by the same pressure step at lower pressures due to the decreased level of tone possessed at those pressures, however, the patterns of responses are similar. Notice that the contraction to 120-150mmHg pressure increase is less than that to 30-60mmHg; one may argue that at higher pressures the vessels are desensitized to pressure increase/stretch. However, this is unlikely because a larger increase in both stretch and tension occurred at the lower pressure, although the applied pressure step was the same (Table 5-1). In other words, the level of stimulation that vessels faced at lower pressure was actually greater than that at higher pressure which, together with the accompanied greater  $Ca^{2+}_i$  response, could explain the differences between the contractions. Moreover, the responses between the two appeared closer if data was shown in the forms of absolute change because arteriolar  $[Ca^{2+}]_i$  was higher and vessels were maintaining smaller diameters at the higher pressure (data not shown).

Presenting the data in relative changes was to eliminate the variations between basal condition of each vessels and as such to provide a clearer display of the results.

In response to greater stretches (e.g. pressure step from 50 to 120mmHg or from 30 to 150mmHg) vessels showed definite biphasic  $[Ca^{2+}]_i$  increases which may indicate a two-component  $Ca^{2+}$  mobilization with each component having different "stretch sensitivity". This biphasic  $[Ca^{2+}]_i$  increase actually also existed in the responses to 30mmHg pressure step (as shown in Table 5-1), however, it was less apparent and obscured in the group data by variations in the time course of the  $[Ca^{2+}]_i$  increase for individual vessels (Figure 5-2). The possible mechanisms for the  $[Ca^{2+}]_i$  increase during arteriolar myogenic and agonist-induced contractions are discussed in the next chapter. An observation that remains very interesting was that, after the transmural pressure increased from 30 to 150mmHg, the vessels did not constrict as quickly as they did in responding to other pressure steps although the increase in  $[Ca^{2+}]_i$  was much higher. It is possible that the vessels have been damaged by the vigorous stretch (about 124% of basal). But, this seems unlikely, or at least the damage is readily reversible, since upon returning pressure to 70mmHg vessels still exhibited a level of spontaneous tone comparable to that occurring prior to the large pressure step (data not shown). Further, similar amount of stretch (i.e. approximately 25%) have been applied to vascular smooth muscle cells without apparent damage (Davis, Donovitz and Hood, 1992). Another explanation is that the vessels have been stretched out so far that the overlap of thick and thin filament is compromised and the smooth muscle enters the descending limb of its length-tension relationship and therefore the force generation appeared to be slow. Such being the case, one would expect a faster shortening velocity once the vessel started to contract. However, this is still not true in our

situation. For example, vessels contracted about 2.1 % between 3 and 5 minute after the pressure step while about 0.1 % between 13 and 15 minute and 0.4 % between 23 and 25 minute. An additional argument against a marked shift to a less favorable position on the length-tension curve is that despite the large magnitude of the pressure step absolute pressures remained within the normal myogenic range. Measurement of MLC phosphorylation levels may help to further interpret this data and will provide an interesting direction for future studies.

Wall tension has been proposed to be the controlled variable in myogenic reactivity (Johnson, 1980), and the studies presented in the previous chapter have shown that steady state  $[Ca^{2+}]_i$  is approximately linearly related to the arteriolar wall tension. It is exciting to notice from the present study that the increase in  $[Ca^{2+}]_i$  following an acute pressure step increase is better correlated with the increase in wall tension than the degree of stretch. This, again, suggests that wall tension may be vitally important in regulation of arteriolar myogenic reactivity. When intraluminal pressure increases vessels are distended and tension increases, the amount of stretch (change in diameter) is related to the tension change because tension is the product of pressure and vessel radius. As vessels constrict to the increased pressure, their diameter decreases and therefore the stimulation is removed (if the stretch is considered the stimulus). One would then expect the  $[Ca^{2+}]_i$  would come back to the basal level; however, this is not what the data indicated. In contrast, if we consider tension as the stimulus and the parameter to control, we would still expect an increased  $[Ca^{2+}]_i$  because the contraction does not fully compensate for the pressure increase and therefore tension is still elevated (i.e. an error signal remains). The relative roles of stretch and tension will be further investigated in

future studies in which the rate of application of the pressure stimulus will be varied (e.g. slow ramp increase).

Using single smooth muscle cells freshly isolated from pig coronary artery, Davis, Meininger and Zawieja (1992) found that progressive stretch is associated with graded, sigmoidal increase in  $[Ca^{2+}]_i$ ; although they did not provide a correlation coefficient between the two variables. Tension was not measured in their study either, it would be very difficult to do so in their system, but, the stretch caused increases in cell length which would be expected to lead to increases in tension. However, the relationship between tension and  $[Ca^{2+}]_i$  may not be necessarily linear, although a significant correlation has been found in the present study. It is possible that a linear relationship is approximated only within the range we tested while this range is but a small portion of the whole relationship, e.g. when stimulation (stretch) is beyond an appropriate physiological range the tension- $[Ca^{2+}]_i$  curve may become exponential. In fact, our data appeared to show this trend when vessels were subjected to a pressure increase from 30 to 150mmHg [as shown in Figure 5-6 (B) represented by the group of points on the right most part of the curve]. More data with greater variation in stimulation magnitude will be needed to define such a relationship.

Another finding in the present studies is that when different stimuli are matched for a similar extent of arteriolar contraction at steady state, the pressure step (50-120mmHg) generated a greater  $[Ca^{2+}]_i$  increase than the agonist (0.1 $\mu$ M NE) stimulation (as shown in Figure 5-10). Therefore, smooth muscle cells appear more sensitive to the effects of  $Ca^{2+}$  in the presence of the agonist. Similar results showing smooth muscle sensitization during agonist stimulated contractions have been reported by other investigators and many studies have

suggested that this sensitization is due to the PKC activated MLC phosphatase inhibition (Katuyama and Morgan, 1993; Kitazawa, et al., 1991; Nishimura, et al., 1990). For example, using  $\alpha$ -toxin permeabilized rabbit portal veins pre-stimulated with  $\text{Ca}^{2+}$  (pCa 5), Kitazawa et al. (1991) showed that phenylephrine and GTP $\gamma$ S decreased the rate of MLC dephosphorylation in presence of a MLCK inhibitor, ML-9. Further, they demonstrated that under  $\text{Ca}^{2+}$ -clamped conditions, addition of GTP $\gamma$ S increased the force generation without any effect on MLCK activity. Experiments from our own laboratory (Hill, et al., 1996) have shown that in  $\alpha$ -toxin permeabilized rat small mesenteric artery preparations the PKC activator, indolactam, induces contraction at constant  $[\text{Ca}^{2+}]_i$  and that this contraction is associated with an increased MLC phosphorylation (e.g. in pCa 7 buffer, 1 $\mu$ M indolactam contracted the vessel to approximately 60% of maximal diameter and the MLC phosphorylation level increased from  $7.5 \pm 1.8 \%$  to  $29.5 \pm 6.6 \%$ ). This, again, supports the hypothetical role of PKC in sensitizing smooth muscle cells by inhibiting MLC phosphatase and demonstrates that such mechanisms are active in small arterial vessels.

In summary, the present study further supports the hypothesis that intracellular calcium and myosin light chain phosphorylation play obligatory roles in arteriolar myogenic reactivity. Vascular wall tension may be a factor of great significance in regulating acute myogenic responses. Agonist (norepinephrine) induced arteriolar contractions are also dependent on the  $\text{Ca}^{2+}$ /CaM activated MLC phosphorylation pathway. However, the differences in temporal responses between myogenic and agonist-induced contractions indicate that different signal transduction pathways are present. The data also suggest that other regulatory mechanisms,

such as the sensitization of the contractile elements perhaps by pathways involving PKC, may contribute to the agonist-induced response.

## CHAPTER VI

### INVOLVEMENT OF EXTRACELLULAR AND INTRACELLULAR $\text{Ca}^{2+}$ IN ARTERIOLAR MYOGENIC AND AGONIST-INDUCED CONTRACTIONS

Cytosolic  $\text{Ca}^{2+}$  may come from two distinct sources: either the extracellular space via influx through various  $\text{Ca}^{2+}$  channels or the intracellular stores by different release mechanisms. The  $\text{Ca}^{2+}$  concentration gradient across the plasma membrane as well as the membrane of intracellular stores (presumable SR) is approximately 10,000 fold with a cytosolic concentration about 100nM under resting conditions. This much lower  $[\text{Ca}^{2+}]_i$  is maintained, mostly, by the  $\text{Ca}^{2+}$ -ATPase and  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchanger on plasma membrane working together with the  $\text{Ca}^{2+}$ -ATPase on intracellular store membrane. While there is evidence to show that the voltage operated  $\text{Ca}^{2+}$  channels on smooth muscle cell membrane account for the  $\text{Ca}^{2+}$  influx to maintain arteriolar basal tone (Harder, et al., 1987; Jackson and Duling, 1989), stretch activated cation channels, recently found in both vascular and visceral smooth muscle cells, have also been reported to contribute to the  $\text{Ca}^{2+}$  influx upon stretch (Kirber, et al., 1988; Davis, Donovitz and Hood, 1992). Although the role of SACs has been speculated to be responsible for causing smooth muscle cell depolarization, to date, there is no direct evidence for their involvement during the pressure induced arteriolar myogenic response (Meininger and Davis, 1992). Receptor operated  $\text{Ca}^{2+}$  channels, which have been demonstrated in other cell

types (Felder, et al., 1992; Llopis, et al., 1992), remain putative and need to be further characterized in smooth muscle cells. Two principal types of intracellular  $\text{Ca}^{2+}$  stores have been implicated in smooth muscle contraction: the  $\text{IP}_3$  sensitive stores and the ryanodine sensitive stores (Iino, 1990), however, the relationship between these stores is still a subject of dispute. Despite a number of studies have demonstrated stretch-induced  $\text{Ca}^{2+}$  release from these stores, evidence for the intracellular  $\text{Ca}^{2+}$  mobilization during arteriolar myogenic contractions is still lacking.

In previous chapters, the role of  $\text{Ca}^{2+}$  and MLC phosphorylation in arteriolar myogenic and agonist-induced contractions has been discussed and the findings support an obligatory role for  $\text{Ca}^{2+}$ /CaM activated MLC phosphorylation in microvascular smooth muscle contraction. However, the question as to the exact source, or sources, of  $\text{Ca}^{2+}$  which are required for activation of the contractile process in microvascular smooth muscle during myogenic activation remain uncertain.

The aim of this chapter was to determine, in isolated skeletal muscle arterioles, the pathways by which  $[\text{Ca}^{2+}]_i$  is increased to initiate arteriolar myogenic and agonist-induced contractions. Comparisons between myogenic and adrenergic agonist-induced contractions were performed as the  $\text{Ca}^{2+}$  requirements of the latter mode of smooth muscle activation has been more widely studied. Further, the experimental approach was designed to provide insight into the relative contribution of voltage-gated  $\text{Ca}^{2+}$  entry, intracellular release and  $\text{Ca}^{2+}$  sensitization to these two distinct modes of activation of microvascular smooth muscle.

## Methods and Experimental Protocols

The methods for vessel isolation, cannulation and  $\text{Ca}^{2+}_i$  measurement were described in detailed in chapter 2. Briefly, isolated rat cremaster first order arterioles were cannulated in a superfusion chamber and initially set at a transmural pressure of 70mmHg in the absence of intraluminal flow. Vessels were superfused with Kreb's buffer and maintained at 34°C throughout each of the experiments.  $[\text{Ca}^{2+}]_i$  was measured using fura-2 as a fluorescent indicator and fluorescence ratio  $R_{340/380\text{nm}}$  was used as a measurement of change in  $[\text{Ca}^{2+}]_i$ . Vessel diameter was measured both using electronic caliper system and the pixel counting technique.

### *Time Course for $\text{Ca}^{2+}$ Measurements*

The following general time course for  $\text{Ca}^{2+}_i$  measurements was used for both pressure and agonist stimulations: immediately prior to the increase of pressure or application of NE, six (6) pairs of fluorescence images from 340nm and 380nm excitation were collected at 10 second intervals. Following stimulation, twelve (12) image pairs were taken at 2 second intervals, then four (4) pairs were collected at 10 second intervals followed by eight (8) pairs at 30 second intervals. A total of thirty (30) pairs of images were taken for each stimulation which covers an approximately 5 minute period post stimulation.

### *Effect of $\text{Ca}^{2+}$ Entry Blockade on Arteriolar Basal Tone and Response to an Acute Increase in Intraluminal Pressure*

To determine the role of voltage-gated  $\text{Ca}^{2+}$  entry in myogenic vasoconstriction, changes in intracellular  $\text{Ca}^{2+}$  and vessel diameter were monitored during an acute pressure

step from 50 - 120 mmHg in the absence and presence of a VOC blocker, verapamil. Verapamil, at a final concentration of 1 and 10  $\mu\text{M}$ , was added to the superfusate reservoir and the arterioles were pre-treated for a period of 20 minutes. Verapamil was used in preference to the dihydropyridine antagonist, nifedipine, as preliminary studies found this latter agent to be adversely affected by the illumination conditions resulting in unstable levels of arteriolar basal tone and fluorescence emission. This problem was not encountered with verapamil. Images were collected according to the general time course described above.  $\text{Gd}^{3+}$  was added along with 10  $\mu\text{M}$  of verapamil to further eliminate  $\text{Ca}^{2+}$  entry, particularly via SACs (Yang and Sachs, 1989).

#### *Effect of $\text{Ca}^{2+}$ Entry Blockade on Adrenergic Agonist-Induced Arteriolar Contraction*

Changes in intracellular  $\text{Ca}^{2+}$  and vessel diameter were monitored during exposure to either norepinephrine at final concentrations of 0.1, 1 and 5  $\mu\text{M}$ . Images were collected using the general time course described above. While the intracellular  $\text{Ca}^{2+}$  release has been suggested to be involved in agonist-induced contractions, contribution of  $\text{Ca}^{2+}$  influx to the intracellular  $[\text{Ca}^{2+}]_i$  is less studied.  $\text{Ca}^{2+}$  channel blockers, Verapamil and  $\text{Gd}^{3+}$ , were added to the superfusate as above to determine the role of  $\text{Ca}^{2+}$  entry in the agonist-induced constriction.

#### *Relationship Between Arteriolar Intracellular $\text{Ca}^{2+}$ Stores Accessed by Caffeine and $\alpha$ -Agonist*

To demonstrate whether overlap existed between the arteriolar caffeine and agonist-accessible  $\text{Ca}^{2+}$  pools studies were conducted after swapping from  $\text{Ca}^{2+}$  containing

extracellular buffer to a Kreb's solution with 0mM  $\text{Ca}^{2+}$  and 2mM EGTA. The superfusion bath was rapidly exchanged (x2) with the 0  $\text{Ca}^{2+}$  solution immediately followed by an exposure to caffeine (20 mM), and after the 340/380nm fluorescence signal declined a 5 $\mu\text{M}$  concentration of phenylephrine (PE) was applied. Following this, vessels were superfused with  $\text{Ca}^{2+}$  containing solution and allowed to re-develop the initial level of spontaneous tone. The experiments were then repeated with the exception the response to phenylephrine was examined before the exposure to caffeine.

#### *Effect of Ryanodine on Arteriolar Tone and Acute Myogenic Reactivity*

To further study the contribution of intracellular  $\text{Ca}^{2+}$  stores to myogenic tone, experiments were conducted using the following protocol:

arterioles were pretreated (10 minutes) with ryanodine (1 or 10 $\mu\text{M}$ ) and then briefly exposed to caffeine (20mM). The exposure of the vessels to caffeine served two aims: 1. test the effectiveness of ryanodine on emptying caffeine accessible stores by inducing a release and 2. further facilitate the action of ryanodine by opening the  $\text{Ca}^{2+}$  release channels because ryanodine functions better when the channels are in an open state (Meissner, 1986). Following the wash out of caffeine (5 minutes), the  $[\text{Ca}^{2+}]_i$  and diameter

responses to an acute 50 - 120 mmHg pressure step was monitored. Experiments were performed in the standard Kreb's solution containing 2.5 mM  $\text{Ca}^{2+}$ .

*Effect of Steady-State Intraluminal Pressure on Caffeine-Induced  $[\text{Ca}^{2+}]_i$  Changes*

After collection of the baseline diameter and 340/380 nm fluorescence ratio measurements, arteriolar segments were exposed to caffeine at a final concentration of 20mM in the presence of the standard Kreb's buffer containing 2.5mM  $\text{Ca}^{2+}$ . The response to caffeine was measured with the vessels set to an intraluminal pressure of either 50 or 120 mmHg after which the vessel was washed with fresh buffer (20 minutes) and the response repeated at the other pressure. The pressure at which the first measurement was taken did not affect, in itself, the subsequent response to caffeine at the other pressure. After completion of the above, vessels were again washed and the responses to caffeine were repeated in the presence of 1 $\mu$ M verapamil to assess the effect of pressure on  $\text{Ca}^{2+}$  entry blockade mediated alteration of caffeine accessible stores.

*$\text{Mn}^{2+}$  Quench Studies*

To provide evidence for  $\text{Ca}^{2+}$  influx and intracellular release during pressure and agonist-induced stimulation the superfusate bathing fura-2 loaded arterioles was rapidly changed from the standard Kreb's solution to a similar buffer containing 1mM  $\text{Mn}^{2+}$  and lacking added  $\text{Ca}^{2+}$ . As shown in the protocol diagram below, within 10~15 seconds of changing the bath the appropriate stimulus was applied to the vessel. Changes in intracellular fluorescence were monitored with excitation at 340nm and 360nm. The rationale behind this approach was  $\text{Mn}^{2+}$  would enter the vessel via the same  $\text{Ca}^{2+}$  influx

pathways mediating basal tone and quench the fluorescence signals emitted following excitation at both 340 and 360 nm. Further, the  $\text{Mn}^{2+}$  would dilute the effects of any residual extracellular  $\text{Ca}^{2+}$ : removal of  $\text{Ca}^{2+}$  would normally require exposure to a buffer containing 0mM  $\text{Ca}^{2+}$  with EGTA, a procedure which rapidly results in depletion of arteriolar intracellular  $\text{Ca}^{2+}$  stores. If, in the presence of the  $\text{Mn}^{2+}$  containing buffer, either a pressure stimulus or agonist released intracellular  $\text{Ca}^{2+}$  this would be evident as an increase in intensity of the 340nm fluorescence signal while little change should be observed for the isobestic 360nm wavelength.

## Results

### *Effect of $\text{Ca}^{2+}$ Entry Blockade on Arteriolar Basal Tone and Response to an Acute Increase in Intraluminal Pressure*

Application of the L-type voltage-operated calcium channel blocker, verapamil, resulted in a dose dependent inhibition of arteriolar basal tone and an accompanying decrease in  $[\text{Ca}^{2+}]_i$ ; (Figure 6-1, measurements were taken under steady states conditions at intraluminal pressures of 50 and 120mmHg in presence of 0, 1, and 10 $\mu\text{M}$  verapamil). For example, at 50mmHg,  $R_{340/348\text{nm}}$  were  $0.83 \pm 0.03\%$  and  $0.78 \pm 0.01\%$  under conditions of control and pre-treatment with 1 $\mu\text{M}$  verapamil corresponding to diameters of  $98.9 \pm 7.3\%$  and  $136.3 \pm 8.1\%$ , respectively. Although vessels were almost maximally dilated in

**Figure 6-1. Effect of  $\text{Ca}^{2+}$  entry blockade on arteriolar steady state basal tone (A) and  $[\text{Ca}^{2+}]_i$  (B). \* indicates significant from basal;  $p < 0.05$ . Data are presented as mean  $\pm$  SEM.**

**A.****B.**

presence of 10 $\mu$ M verapamil (compared with in 0mM Ca<sup>2+</sup>/EGTA solution; e.g. 158.2  $\pm$  13.5 $\mu$ m vs. 169.5  $\pm$  8.7 $\mu$ m at 50mmHg), steady-state [Ca<sup>2+</sup>]<sub>i</sub> was still significantly higher ( $p < 0.05$ ) than when vessels had been superfused with 0mM Ca<sup>2+</sup>/EGTA solution ( $R_{340/348nm}$  were 0.68  $\pm$  0.03 vs. 0.44  $\pm$  0.1 at 50mmHg, Figure 6-1).

Under control conditions, as shown in the previous chapter, following an acute 50-120mmHg increase in intraluminal pressure the arterioles showed an initial phase of distention which was paralleled by a rapid increase in [Ca<sup>2+</sup>]<sub>i</sub>. This phase was followed by active contraction of the arterioles during which [Ca<sup>2+</sup>]<sub>i</sub> remained significantly greater than that in the basal period (Figure 6-2). The calcium channel blocker verapamil (1 or 10 $\mu$ M) abolished the pressure-induced vasoconstriction in response to the 50-120 mmHg pressure step. In apparent contrast to the diameter response [Ca<sup>2+</sup>]<sub>i</sub> increased significantly from the basal of each condition, albeit transiently, in response to the pressure stimulus both following 1 and 10 $\mu$ M verapamil treatment (Figures 6-2 and 6-3). Addition of Gd<sup>3+</sup> (10 $\mu$ M in presence of 10 $\mu$ M verapamil) did not show further inhibition of the arteriolar responses (Figures 6-1, 6-2 and 6-3).

#### *Effect of Ca<sup>2+</sup> Entry Blockade on Adrenergic Agonist-Induced Contraction*

Arterioles showed dose-dependent increases in [Ca<sup>2+</sup>]<sub>i</sub> and extent of vasoconstriction to norepinephrine (0.1, 1.0 and 5 $\mu$ M; Figures 6-4, 6-5 and 6-6). The change in intracellular Ca<sup>2+</sup> was typically biphasic with a marked early transient increase followed by a decline to a steady-state level; while the vasoconstriction was largely monophasic being maintained despite the decline in Ca<sup>2+</sup> from peak levels (also refer to chapter 5 for another set of similar experiment under control conditions). The effect of Ca<sup>2+</sup> entry blockade appeared to have a stronger effect on steady-state [Ca<sup>2+</sup>]<sub>i</sub> and this

**A.****B.**

effect is more obvious in the responses to low concentrations of agonist stimulation (Figure 6-7). Despite the verapamil dose-dependent arteriolar tone inhibition, in 10 $\mu$ M verapamil, 5 $\mu$ M NE still caused a significant contraction but this contraction was abolished by the further addition of 10 $\mu$ M Gd<sup>3+</sup> to the superfusate (Figure 6-8) which decreased the basal [Ca<sup>2+</sup>]<sub>i</sub> to a lower level ( $R_{340/380nm}$  were  $0.65 \pm 0.05$  vs.  $0.60 \pm 0.06$ , respectively;  $p < 0.05$ ).

#### *Relationship Between Arteriolar Intracellular Ca<sup>2+</sup> Stores Accessed by Caffeine and $\alpha$ -Agonist*

In the absence of extracellular Ca<sup>2+</sup>, both caffeine (20mM) and PE (5 $\mu$ M) induced Ca<sup>2+</sup> releases from intracellular stores as demonstrated by the rapid increases in the fluorescence ratio  $R_{340/380nm}$  (Figures 6-9 and 6-10), and further the caffeine mediated release was substantial even when PE induced Ca<sup>2+</sup> mobilization was diminished with repeated challenges (Figure 6-9) or as a result of prolonged exposure to 0Ca<sup>2+</sup>/EGTA solution (Figure 6-10). However, PE failed to demonstrate further Ca<sup>2+</sup> increases following a caffeine stimulation (Figure 6-9). The decreases in magnitude of fluorescence ratio for both caffeine and PE stimulations, with the superfusion time in 0 Ca<sup>2+</sup>/EGTA buffer, suggests a gradual depletion of the intracellular Ca<sup>2+</sup> store occurs when arterioles are subjected to 0mM extracellular Ca<sup>2+</sup> (Figure 6-10).

#### *Effect of Ryanodine on Arteriolar Tone and Acute Myogenic Reactivity*

Consistent with the notion that ryanodine activates Ca<sup>2+</sup> release channels on intracellular stores and locks them in an open position, caffeine induced Ca<sup>2+</sup> release was attenuated following ryanodine pre-treatment of the arterioles (peak values for

Figure 6-7. Effect of  $\text{Ca}^{2+}$  entry blockade on arteriolar maximal and steady-state  $\text{Ca}^{2+}$  response to 0.1 $\mu\text{M}$  (A), 1 $\mu\text{M}$  (B) and 5 $\mu\text{M}$  (C) norepinephrine stimulation. The effect of  $\text{Gd}^{3+}$  was tested in the presence of 10 $\mu\text{M}$  verapamil. Data are normalized to the basal under each conditions and presented as mean  $\pm$  SEM, n = 5. \* indicates significant from basal;  $p < 0.05$ .

Top panel shows the stored  $\text{Ca}^{2+}$  mobilizations performed in the absence of extracellular  $\text{Ca}^{2+}$  with 20mM caffeine followed by 5 $\mu\text{M}$  phenylephrine. Bottom panel shows the stored  $\text{Ca}^{2+}$  mobilizations performed in the absence of extracellular  $\text{Ca}^{2+}$  with 5 $\mu\text{M}$  phenylephrine followed by another 5 $\mu\text{M}$  phenylephrine then 20mM caffeine. Dotted line in the bottom panel indicates the level of  $[\text{Ca}^{2+}]_i$  rise caused by caffeine releasing of intracellular stores as shown in the top panel.

Figure 6-10. Representative tracings showing the time course for the depletion of intracellular  $\text{Ca}^{2+}$  stores accessed by agonist and caffeine in the absence of extracellular  $\text{Ca}^{2+}$ . Vessels were challenged by 5 $\mu\text{M}$  PE at 1, 2, 3, 4, and 5 minutes after changing the superfusate from normal Krebs's buffer (with 2.5mM  $\text{Ca}^{2+}$ ) into a buffer containing 0mM  $\text{Ca}^{2+}$  and 2mM EGTA. Caffeine were applied following the PE stimulation at 3 and 5 minutes. Dotted line indicates the time extracellular  $\text{Ca}^{2+}$  was changed.

fluorescence ratio were  $2.41 \pm 0.19$  vs.  $1.82 \pm 0.24$ ;  $n = 4$ ,  $p < 0.05$ ). The rate of  $[Ca^{2+}]_i$  increase following an acute 50-120mmHg pressure step was slower in vessels subjected to ryanodine pre-treatment (time required to reach half-maximum level were  $8.5 \pm 0.1$  and  $14.8 \pm 2.0$  seconds respectively,  $p < 0.05$ ), however, the arteriolar basal tone was potentiated ( $p = 0.02$ ) and vessels still exhibited myogenic contractions (Figure 6-11). While 1 $\mu$ M ryanodine caused a maintained constriction of the vessel higher concentrations (10 $\mu$ M) did not appear to have further effect on vessel diameter and, similarly to the lower concentration, did not prevent the pressure-induced vasoconstriction.

#### *Effect of Steady-State Intraluminal Pressure on Caffeine-Induced $[Ca^{2+}]_i$ Changes*

Under control conditions, caffeine (20mM) caused comparable  $[Ca^{2+}]_i$  increases at 50 and 120mmHg, however, the vessels demonstrated a significantly greater contraction at the lower pressure of 50mmHg (figure 6-12). In the presence of VOC blocker, verapamil (1 $\mu$ M), the rise in  $[Ca^{2+}]_i$  was significantly decreased at 120mmHg ( $p < 0.02$ ) compared with that occurring at 50mmHg which remained similar to that under control condition, while the arteriolar contraction to caffeine continued to be significantly less ( $p < 0.001$ ) at 120mmHg than that at 50mmHg (Figure 6-12). The latter data suggests that in the presence of verapamil the higher pressure (120mmHg) may partially deplete the caffeine-accessible  $Ca^{2+}$  store.

#### *Mn<sup>2+</sup> Quench Studies*

Following replacing the normal superfusate with a buffer containing 0mM  $Ca^{2+}$ /1mM  $Mn^{2+}$ , a dilation of the arterioles was observed with a rapid decrease in

fluorescence intensities indicating a decrease in  $[Ca^{2+}]_i$  (by 340nm excitation) and a  $Mn^{2+}$  influx (by 340nm and 360nm excitations; Figure 6-13). 10~15 seconds after swapping into the 0mM  $Ca^{2+}$ /1mM  $Mn^{2+}$  buffer, a pressure step increase from 50 to 120mmHg did not cause a detectable increase in fluorescence intensity of the 340nm image (Figures 6-13 and 6-14) while a subsequent caffeine (20mM) stimulation demonstrated a rapid increase that decayed with time (Figure 6-13). Similarly, at the time point (10~15 seconds following buffer change) when pressure increase did not affect the fluorescence intensity of 340nm image, 5 $\mu$ M PE was capable of generating a transient increase in intensity of 340nm signal indicating  $Ca^{2+}$  release (Figure 6-14).

### Discussion

By showing a decreased level of  $[Ca^{2+}]_i$  in the presence of a L-type voltage-operated  $Ca^{2+}$  channel blocker, verapamil, results from the present study, besides giving supportive evidence to the notion that  $Ca^{2+}$  influx through plasma membrane is required for the maintenance of arteriolar basal tone, further demonstrated that myogenic contraction to transmural pressure increase depends on an extracellular  $Ca^{2+}$  source. While intracellular  $Ca^{2+}$  release may also be involved in these events, it does not appear to be mandatory. On the other hand, NE induced vessel contraction showed less of a dependency on  $Ca^{2+}$  entry and further implicated the involvement of a  $Ca^{2+}$  sensitizing mechanism. The ryanodine sensitive intracellular  $Ca^{2+}$  store appears to be larger than the agonist-sensitive (presumably  $IP_3$  stimulated)  $Ca^{2+}$  store in rat cremaster first order arterioles.

The presence of extracellular  $Ca^{2+}$  as a necessity for the maintenance of arteriolar tone has been demonstrated by a number of investigators using in vivo preparations (Harder, et al.,

**Figure 6-13. Representative tracings detecting arteriolar intracellular  $\text{Ca}^{2+}$  release during pressure step-increase and a following caffeine stimulation. 1987; Jackson and Duling, 1989), however,  $[Ca^{2+}]_i$  were not measured in those studies. With the use of fluorescent  $Ca^{2+}$  indicator, fura-2, we were able to more closely examine this issue. A decrease in  $[Ca^{2+}]_i$  was found in a dose dependent manner to the addition of verapamil to superfusing solution, which confirmed the inhibitory effect of verapamil on  $Ca^{2+}$  entry. With that, the isolated arterioles also lost their basal tone verapamil dose dependently (Figure 6-1). The arteriolar myogenic contraction is totally inhibited by  $1\mu M$  verapamil when the vessels still exhibited certain amount of spontaneous tone (Figure 6-2), indicating, at least for the tone developed in the presence of active VOC's, less  $Ca^{2+}$  is required to maintain it than to initiate a myogenic contraction.

Laher et al. (1988) showed that stretching of rabbit facial vein smooth muscle will induce a maintained active tone which is associated with an increase in  $Ca^{2+}$  influx. Further, by using a dihydropyridine VOC blocker (PN 200-110), they demonstrated that this  $Ca^{2+}$  influx is not through the VOCs and hence suggested a direct entry pathway. More recently, stretch activated  $Ca^{2+}$  channels were reported to be present in vascular smooth muscle cells (Davis, Donovitz and Hood, 1992) and have been implicated to be involved in the myogenic response (Meininger and Davis, 1992). In the present study, the observed transient  $Ca^{2+}$  increase in presence of VOC blockade, verapamil, may be due to the  $Ca^{2+}$  entry through these SACs (Figures 6-2, 6-3). However, SACs alone may not be able to totally explain the transient  $Ca^{2+}$  increase, because a  $[Ca^{2+}]_i$  increase was observed even in the presence of  $Gd^{3+}$ , a trivalent cation that has been reported to block SACs (Yang and Sachs, 1989). It is possible that at the concentration we used ( $10\mu M$ ),  $Gd^{3+}$  does not provide a total inhibition of the SACs although

it has been shown that this concentration is sufficient to block the SACs in some other cell types, e.g. frog kidney proximal cells and *Xenopus* oocytes (Robson and Hunter, 1994; Yang and Sachs, 1989). The observations that  $Gd^{3+}$  did further decrease  $[Ca^{2+}]_i$  and have an effect on the NE response suggest that  $Gd^{3+}$  reached the tissue and, at that concentration, could be effective. However, electrophysiological studies will be needed to determine the effective concentration for  $Gd^{3+}$  to block vascular smooth muscle SACs.

Kwan et al. (1990) has shown that another trivalent cation  $Ca^{2+}$  channel blocker,  $La^{3+}$ , has an effect on fura-2 fluorescence excitation/emission similar to  $Ca^{2+}$ . If this also applies to  $Gd^{3+}$ , the transient increase in fluorescence ratio (which is usually taken as an indication of  $[Ca^{2+}]_i$ ) could, at least partly, be explained by the  $Gd^{3+}$  entering into the cell through SACs upon pressure increase. So far, there is no data show the permeability of vascular smooth muscle SACs to  $Gd^{3+}$ .

$Ca^{2+}$  entry through T-type VOCs is also an alternative mechanism for this transient increase. However, the T-type VOCs are not found to be present in all smooth muscle cell types (Nelson, et al., 1990) and to date there has been no direct evidence for their functioning in cremaster first order arterioles. The observation that  $Gd^{3+}$  did not block this increase argues against the role of T-type VOCs in this situation because this nonspecific  $Ca^{2+}$  channel blocker has been demonstrated to block both T- and L-type VOCs at lower concentrations (Biagi and Enyeart, 1990; Song et al., 1992). Moreover, their low conductance ( $\sim 1/3$  of that of L-type VOC) and short lasting (20-50ms) characteristics plus their wide activation range (positive to -70mV) also makes T-type VOCs less likely to be a major contributor to this  $Ca^{2+}$  rise (Tsien, et al., 1988).

Another explanation to the transient  $[Ca^{2+}]_i$  increase is that  $Ca^{2+}$  has been released from intracellular stores following an acute pressure step stimulation. Although the results from the  $Mn^{2+}$  studies do not favor this suggestion (Figures 6-13 and 6-14), it is possible that this technique is not sensitive enough to detect the relative smaller release induced by pressure stimulation. Another observation from the present studies also support the possibility of intracellular  $Ca^{2+}$  release: the  $[Ca^{2+}]_i$  rise was slower when the intracellular stores were emptied by ryanodine (time required to reach half-maximum level were  $8.5 \pm 0.1$  and  $14.8 \pm 2.0$  seconds respectively,  $p < 0.05$ ). This idea is also indirectly supported by the findings of other investigators, e.g. depolarization alone requires 30-60 seconds to produce a detectable change in  $[Ca^{2+}]_i$  in bovine coronary arterial cells (Wagner-Mann, et al., 1991). Further, the diffusion of  $Ca^{2+}$  in the cytosol is much slower than that of any other second messengers, due to the presence of a large number of almost immobile  $Ca^{2+}$  binding sites (Allbritton, et al., 1992). More direct evidence came from the reports that stretch-induced intracellular  $Ca^{2+}$  release being observed both in single smooth muscle cells (Davis, Meininger and Zawieja, 1992) and in isolated arterial tissues (Tanaka, et al., 1993). For example, Davis, Meininger and Zawieja (1992) found that, when applying stretch to single pig coronary arterial smooth muscle cells in a  $Ca^{2+}$  free solution, a 24% stretch could cause  $Ca^{2+}$  release while a 10% stretch showed no change in  $[Ca^{2+}]_i$ . It therefore appears that there is a threshold for the intracellular  $Ca^{2+}$  release or the two phases of  $Ca^{2+}$  rise have different "stretch-sensitivities". Although the cellular mechanism for this  $Ca^{2+}$  release is not clear at this time, the idea of  $Ca^{2+}$  release is consistent with the suggestion that PLC activation is involved in myogenic reactivity (Narayanan, et al., 1994; Osol, 1995). Stretch has been recently reported to cause a significant increase in PLC

activity in aortic smooth muscle within 275~375ms (Matsumoto, et al., 1995). However, further studies are still needed to determine whether similar activation is present in myogenic response because aortic rings, used in the above experiments, rarely show stretch induced contraction.

It is interesting to notice that the maintained opening state of  $\text{Ca}^{2+}$  channels on intracellular  $\text{Ca}^{2+}$  store, by ryanodine treatment resulted in a greater spontaneous tone in these arterioles while the increase in  $[\text{Ca}^{2+}]_i$  was not significant. However, since a relatively higher  $R_{340/380}$  level was consistently observed in each of the experiments in the presence of ryanodine, statistical significance may be evident with additional experiments (statistics were performed with  $n=4$  observations). On the other hand, this unaffected  $\text{Ca}^{2+}$  level can possibly be explained by the superficial buffer barrier model that an empty store will have the greatest buffering capacity for  $\text{Ca}^{2+}$  entering across the plasma membrane. Moreover, there might also be an enhanced  $\text{Ca}^{2+}$  efflux mechanism that helps to remove the cytosolic  $\text{Ca}^{2+}$  in this specific situation.

Although the intracellular  $\text{Ca}^{2+}$  release is not required for the arteriolar myogenic contraction and basal tone maintenance (Figure 6-11), it does not necessarily contradict the suggestion that PLC can be activated following an acute pressure increase, as in the situation of stretching of smooth muscle cells. PLC activation generally produce two major cellular messengers,  $\text{IP}_3$  and DAG. While  $\text{IP}_3$  might not be able to demonstrate its effect due to the emptiness of intracellular stores (supported by the observation that NE resulted little increase in  $R_{340/380\text{nm}}$  in presence of ryanodine, data not shown), the role of PKC activated by DAG in the myogenic contraction can not be ruled out. There has been evidence showing that

activation of PKC enhances the stretch-induced tone and PKC inhibitors attenuate myogenic responsiveness in isolated arterial preparations (Hill, et al., 1990; Laher and Bevan, 1987).

The observations that 1 $\mu$ M verapamil (and 1 $\mu$ M nifedipine, data not shown) significantly inhibited spontaneous tone and blocked myogenic constriction are at variance with the previous finding that VOCs are not the prime determinant of constrictor response to acute increase in intravascular pressure (Hill and Meininger, 1994). Although both studies used rat cremaster arterioles, the previous study was carried out *in vivo* while the present study employed an *in vitro* isolated preparation. Additional factors which make comparison of these studies difficult include, 1. data from the *in vivo* study was based on the response of third order arterioles instead of the first order vessels (which were used in this *in vitro* preparation); and 2. the first order arterioles do not exhibit spontaneous tone in such preparations probably as a result of the extensive surgery required for preparations of the cremaster muscle for *in vivo* microscopy (Hill, et al., 1990). Therefore, the inconsistency may come from either the differences in tissue preparation, *in vivo* vs. *in vitro*, or from the differences in the size or branch order of the vessels because functional variation appears to occur at different levels within a microvascular network.

Arterioles stimulated with norepinephrine showed a transient spike followed by a sustained elevation of  $[Ca^{2+}]_i$  which is consistent with the other reported studies (Hill, et al., 1990; Meininger, et al., 1990). It is interesting to find from the present studies that while the transient increase in  $Ca^{2+}$  was less affected by the  $Ca^{2+}$  channel blockers, the sustained elevation was significantly attenuated (Figures 6-5, 6-6 and 6-7). Moreover, higher concentration of NE (5 $\mu$ M) showed a greater ability to increase  $[Ca^{2+}]_i$  during the plateau phase even in the

presence of 10 $\mu$ M verapamil, however, this was abolished by the further addition of 10 $\mu$ M Gd<sup>3+</sup> and so was the arteriolar contraction. Although the specific mechanisms for Gd<sup>3+</sup> blocking Ca<sup>2+</sup> channels are not clear, it is likely that this cation acts as a non-specific, competitive blocker that also block other Ca<sup>2+</sup> channels (Song, et al, 1992). The observation that Gd<sup>3+</sup> blocked the NE induced Ca<sup>2+</sup> increase that was not sensitive to VOC blockade implicates, as some investigators suggested in other tissues, that receptor operated Ca<sup>2+</sup> channels may be present in cremaster first order arteriolar smooth muscle cells. Moreover, the contractions demonstrated following an agonist stimulation under an similar condition when no pressure-induced contraction occurred, e.g. a similar [Ca<sup>2+</sup>]<sub>i</sub> increase in presence of 1 $\mu$ M verapamil, gave additional supports to the notion of smooth muscle sensitization in response to agonists.

It has been suggested that distention of vascular smooth muscle or elevation of transmural pressure will enhance the arterial response to agonist (Lombard, et al., 1990; Nilsson and Sjoblom, 1985). Further, the observed higher [Ca<sup>2+</sup>]<sub>i</sub> at elevated pressures, as presented in the studies in chapter 4, may suggests a more active state of arterioles. However, the observation that arteriolar contractile responses to caffeine (20mM) at 120mmHg smaller than at 50mmHg (Figure 6-12) argues against the proposition of arteriolar sensitization at higher pressures. However, the variation may be due to the different stimuli applied, caffeine vs. NE, because caffeine also inhibits phosphodiesterase and results in an elevated cAMP/cGMP level(s) and consequent vasodilatation.

In summary, results from the present studies demonstrate that while Ca<sup>2+</sup> entry from extracellular compartment, mostly via VOCs, is a mandatory process for maintaining arteriolar basal tone and the initiation of myogenic contraction, the release of Ca<sup>2+</sup> from

intracellular stores is not an absolute requirement. However, the  $\text{Ca}^{2+}$  release may actually be involved during a myogenic response especially when the stimulus (pressure increase/stretch) is relatively larger as, in the presence of  $\text{Ca}^{2+}$  channel blockers, a transient  $\text{Ca}^{2+}$  increase was observed in response to an acute pressure increase from 50 to 120mmHg. On the other hand, NE induced arteriolar contractions showed more dependency on intracellular store release while the  $\text{Ca}^{2+}$  entry may play a more important role in the sustained phase of contraction instead of force initiation. Further, the  $\text{Ca}^{2+}$  entry following an agonist stimulation may include a mechanism, e.g. receptor operated channels, that is not activated during myogenic contractions.

## CHAPTER VII

### CONCLUDING STATEMENTS AND FUTURE DIRECTIONS

Results from the studies presented in this thesis provided substantial evidence to demonstrate the obligatory roles of  $[Ca^{2+}]_i$  and MLC phosphorylation in arteriolar myogenic reactivity and further demonstrate the major contribution of  $Ca^{2+}$  entry from the extracellular environment. The studies also provided evidence to suggest that agonist-induced arteriolar contractions are dependent on the  $Ca^{2+}$ /CaM activated MLCK pathway with possible modulation by other mechanisms. Additional results support the notion that contractile protein expression in resistance vessels may also underlie differences in reactivity of large and small vessels and therefore could conceivably contribute to myogenic reactivity. These conclusions, and some avenues for future research, are discussed below together with a summary of the cellular events involved in the genesis of arteriolar tone and myogenic reactivity.

#### *Contractile Isoform Expression May Set the Structural Basis for Arteriolar Myogenic Reactivity*

The results from the present study demonstrated differences in contractile isoform expression in more active vessels. For example, the expression of  $\alpha$ -actin isoform is inversely correlated with vessel diameter perhaps consistent with functional variations between vessels of different sizes. Similarly, arterial vessels showed more  $\alpha$ -actin than did the corresponding venous vessels. Therefore, myogenic reactivity, which is most prevalent

in small arteries and arterioles may, in part, relate to differences in structural composition of proteins participating in the contractile process.

Structural differences are not limited to the level of contractile proteins but also other aspects such as intracellular  $\text{Ca}^{2+}$  stores, cell membrane composition, the distribution and characteristics of ion channels [e.g.  $\text{K}^+$  channels which have been implicated to serve as feedback mechanism during myogenic reactivity (Nelson, 1993)] et al.. Future studies directed towards revealing these differences, if they do exist, will help to further understand the dependency of cell functions (e.g. myogenic reactivity) on structural variations and signal transduction pathways.

*Wall Tension or a Related Parameter May Be the Sensing Factor and the Controlled Variable During Myogenic Reactivity.*

The present studies suggest that the effect of intraluminal pressure changes may be detected, by the arterioles, as alterations in wall tension or a related variable, and also, wall tension appears to be a regulatory factor that the arterioles attempt to maintain at a controlled level.

Although a number of studies, including the present experiments, suggest the regulatory role of wall tension in myogenic reactivity a definite conclusion has not been reached. Basic questions still remain such as: how is the wall tension being sensed, where is the site of this hypothetical tension sensor, and how the mechanical signal is translated into a chemical process. In the present studies, when arteriolar responses to acute pressure increases were examined, increases in wall tension were always associated with abrupt stretch of the vessel which made it difficult to interpret the results (i.e. what is the

effect of change in tension vs. change in length). Further experiments need to be designed in such a way that these two related factors can be separated to allow the role of wall tension to be specifically addressed. For example, the study of arteriolar responses to slow (ramp) increases in transmural pressure when no obvious change in vessel diameter occurs.

*[Ca<sup>2+</sup>]<sub>i</sub> and MLC Phosphorylation Play Obligatory Roles in Arteriolar Myogenic Reactivity*

Data presented in this thesis demonstrated that increased wall tension (elevated intraluminal pressure) is associated with increases in [Ca<sup>2+</sup>]<sub>i</sub> and MLC phosphorylation. Further, the MLCK inhibitor, ML-7, inhibits myogenic tone by dissociating the Ca<sup>2+</sup> response from arteriolar contraction. These data suggest that increases in [Ca<sup>2+</sup>]<sub>i</sub> and MLC phosphorylation are obligatory requirements for the setting of pressure-dependent steady-state arteriolar spontaneous tone. Moreover, the arteriolar myogenic contraction to an acute pressure increase also showed dependencies on [Ca<sup>2+</sup>]<sub>i</sub> and MLC phosphorylation. Additional studies that examine this pathway in the arteriolar responses to pulsatile pressures or in the presence of intraluminal flow will provide further information more closely related to the *in vivo* physiological conditions.

*Extracellular Space is the Major Source for the Increased Ca<sup>2+</sup> During Myogenic Reactivity.*

The extracellular source, rather than the intracellular stores, is most important in providing of the Ca<sup>2+</sup> required for the maintenance of arteriolar basal tone and the initiation of myogenic contraction. This conclusion is drawn from two lines of experimental evidence: 1) blockade of VOCs with verapamil abolished the spontaneous tone and the constriction to acute

pressure increase; 2) arterioles still exhibited basal tone and myogenic contraction with an observed  $[Ca^{2+}]_i$  rise when intracellular  $Ca^{2+}$  stores were depleted with ryanodine treatment. While  $Ca^{2+}$  entry from the extracellular environment, largely via VOCs, is a mandatory process,  $Ca^{2+}$  release from intracellular stores may play a supportive role in myogenic reactivity, especially during the response to acute pressure increases. This is suggested by the observation of transient increase in  $[Ca^{2+}]_i$  in response to pressure step while the  $Ca^{2+}$  entry was blocked in presence of verapamil and  $Gd^{3+}$ . While evidence for the exact mechanism for this  $Ca^{2+}$  release is not provided from the present studies, stretch activated PLC activity could be a possible candidate as suggested by studies from other investigators (Matsumoto, et al., 1995; Osol, 1995). Another possible mechanism is  $Ca^{2+}$  mobilization due to the  $Ca^{2+}$  entry through SACs, via a calcium induced calcium release mechanism, upon stretch (pressure increase). Although the present studies show that  $Ca^{2+}$  entry blockade abolished the arteriolar response to acute pressure increase, the data were acquired when vessels were significantly dilated with lower levels of  $[Ca^{2+}]_i$  because of the prolonged exposure to  $Ca^{2+}$  channel blockers. In order to examine this issue more closely, future experiments need to be designed so that the arteriolar responses to acute pressure increases can be monitored immediately after the  $Ca^{2+}$  entry blockade while the  $[Ca^{2+}]_i$  and vessel diameter are not significantly affected. Moreover, the mechanism for VOC activation during myogenic contraction is another subject that needs to be further examined. Current evidence suggests both direct activation by stretch and, indirectly, by the cell depolarization due to the cation entry through SACs upon stretch (Davis, Donovitz and Hood, 1992; McCarron, et al., 1995).

*Dependency of the  $\text{Ca}^{2+}$ /CaM Activated MLCK Pathway is Modulated by Other Mechanisms During Agonist-Induced Arteriolar Contraction*

$\alpha$ -adrenergic agonist, norepinephrine, induced arteriolar contraction also depends on the increase in  $[\text{Ca}^{2+}]_i$  and MLC phosphorylation as demonstrated in the present studies. However, the distinct patterns in temporal responses between myogenic and agonist-induced contraction indicate that different signal transduction pathways are present. For example, other regulatory mechanisms, such as the sensitization of the contractile elements perhaps by pathways involving PKC, may contribute to the agonist-induced arteriolar response. While the role of PLC is less obvious during myogenic contractions, activation of PLC in arteriolar responses to agonist stimulation appears more important. Arteriolar contraction showed much stronger dependency on  $\text{Ca}^{2+}$  release from intracellular stores, especially for the initiation of the contraction. The observation that  $\text{Gd}^{3+}$ , a non-specific  $\text{Ca}^{2+}$  channel blocker, inhibited arteriolar contraction to agonist indicates that a  $\text{Ca}^{2+}$  entry mechanism which is not exhibited in the myogenic contractions, possibly receptor-operated  $\text{Ca}^{2+}$  channels as suggested by others, is involved in the agonist-induced contractions.

*Relationship with Other Vasoregulatory Mechanisms*

Since these vessels are also under neuronal control and the influence of local metabolism, it is important to examine the interactions that occur between arteriolar responses to pressure changes and to metabolic/agonist stimulation. The interaction between endothelium, which underlies the smooth muscle cells on vessel wall, and vascular smooth muscle is another important issue need to be considered. These studies will help us in better understanding the arteriolar functions and characteristics under *in situ* conditions.

### *Signal Transduction Pathways Underlying Myogenic Reactivity*

Based on the results from this thesis and published studies from other investigators, a schematic diagram is presented in Figure 7-1 to illustrate the signaling pathways involved in the arteriolar myogenic responses. Stretch of smooth muscle cells or an increase in tension, as would be expected to occur when vascular pressure increases, leads to the opening of stretch activated channels and allows cations (including  $\text{Ca}^{2+}$ ) to enter from extracellular space. This event may serve several purposes: 1) it may cause membrane depolarization, due to the influx of cations, and subsequently activation of voltage operated  $\text{Ca}^{2+}$  channels (recent evidence suggested that VOC can also be directly modified by stretch); 2) the  $\text{Ca}^{2+}$  came in through this channel may induce a  $\text{Ca}^{2+}$  release from intracellular stores; 3) This  $\text{Ca}^{2+}$ , itself, also contribute to the increase in  $[\text{Ca}^{2+}]_i$ . The opening of VOCs allows more  $\text{Ca}^{2+}$  to enter and further increase  $[\text{Ca}^{2+}]_i$ .  $\text{IP}_3$ , together with DAG, is generated by PLC which is somehow activated following the stretch. Binding of  $\text{IP}_3$  to its receptors on SR will cause a  $\text{Ca}^{2+}$  release which may represent another mechanism for the  $[\text{Ca}^{2+}]_i$  rise. While all these events contribute to the elevation in  $[\text{Ca}^{2+}]_i$  and lead to MLC phosphorylation, DAG activated PKC may exert its inhibitory effect on MLC phosphatase, hence, potentiates the levels of MLC phosphorylation and cause the sensitization of contractile apparatus to  $\text{Ca}^{2+}$ . The smooth muscle cell contraction then becomes an inevitable consequence.

## VITA

**Name:** Hui Zou  
SSN: 223-61-9521

**Address:** University of Massachusetts      63 Frank street  
Department of Physiology      Apartment 86  
Worcester, MA 01605      Worcester, MA 01604

**Date of Birth:** March 14, 1964  
Tianjin, China

**Education:**

1995      Doctor of Philosophy  
Eastern Virginia Medical School and Old Dominion University  
(Biomedical Sciences)  
Field of Study: Microvascular Physiology  
Thesis: Cellular Mechanisms underlying Basal Tone and Myogenic  
Reactivity in Isolated Arterioles  
Advisor: Michael A.Hill, Ph. D

1989      Master of Engineering  
Tianjin University, China  
Field of Study: Biomedical Engineering and Instrumentation  
Thesis: Design of an ECG monitor with Functions of Pacing and  
Defibrillation.  
Advisor: Ming Shi Wang

1986      Bachelor of Engineering  
Tianjin University, China  
Field of Study: Biomedical Engineering and Instrumentation  
Thesis: Design of a Digital Thermometer  
Advisor: Ming Shi Wang

### Honors:

1992-1995      3 years Graduate Fellowship  
Eastern Virginia Medical School

### Professional Society Memberships:

American Physiology Society
