Measurements of electroweak form factors determine nucleon spatial structure, and deep inelastic scattering (DIS) of leptons off the nucleon measures parton distribution functions, which determine longitudinal momentum distributions. The demonstration by Ji [1], Radlyushkin [2], and Mueller et al. [3], of a formalism to relate the spatial and momentum distributions of the partons allows the exciting possibility of determining spatial distributions of quarks and gluons in the nucleon as a function of the parton wavelength. These new structure functions, now called generalized parton distributions (GPD), became of experimental interest when it was shown [1] that they are accessible through deeply virtual Compton scattering (DVCS) and its interference with the Bethe-Heitler (BH) process (Fig. 1). Figure 1 presents our kinematic nomenclature. DVCS is defined kinematically by the

We present the first measurements of the $\vec{e}p \rightarrow e\gamma p$ cross section in the deeply virtual Compton scattering (DVCS) regime and the valence quark region. The $Q^2$ dependence (from 1.5 to 2.3 GeV$^2$) of the helicity-dependent cross section indicates the twist-2 dominance of DVCS, proving that generalized parton distributions (GPDs) are accessible to experiment at moderate $Q^2$. The helicity-independent cross section is also measured at $Q^2 \approx 1.36 \pm 0.3 \text{ GeV}^2$. We present the first model-independent measurement of linear combinations of GPDs and GPD integrals up to the twist-3 approximation.

Measurements of electroweak form factors determine nucleon spatial structure, and deep inelastic scattering (DIS) of leptons off the nucleon measures parton distribution functions, which determine longitudinal momentum distributions. The demonstration by Ji [1], Radlyushkin [2], and Mueller et al. [3], of a formalism to relate the spatial and momentum distributions of the partons allows the exciting possibility of determining spatial distributions of quarks and gluons in the nucleon as a function of the parton wavelength. These new structure functions, now called generalized parton distributions (GPD), became of experimental interest when it was shown [1] that they are accessible through deeply virtual Compton scattering (DVCS) and its interference with the Bethe-Heitler (BH) process (Fig. 1). Figure 1 presents our kinematic nomenclature. DVCS is defined kinematically by the
Collaborations measured the cross section for $e p \to e p \gamma$, including the DVCS and Bethe-Heitler (BH) amplitudes. The external momentum four-vectors are defined on the diagram. The virtual photon momenta are $q = k - k'$ in the DVCS- and $\Delta = q - q'$ in the BH-amplitudes. The invariants are: $W^2 = (q + p)^2$, $Q^2 = -q^2 > 0$, $t = \Delta^2$, $x_{bj} = Q^2/(2p \cdot q)$, and the DVCS scaling variable $\xi = -q^2/(q \cdot P) \approx x_{bj}/(2 - x_{bj})$, with $q = (q + q')/2$ and $P = p + p'$.

limit $-t \ll Q^2$ and $Q^2$ much larger than the quark confinement scale.

The factorization proofs [4,5] confirmed the connection between DVCS and DIS. Diehl et al. [6] showed that the twist-2 and twist-3 contributions in the DVCS-BH interference terms (the first two leading orders in $1/Q$) could be extracted independently from the azimuthal dependence of the helicity-dependent cross section. Burkardt [7] showed that the $t$ dependence of the GPDs is the Fourier conjugate to the transverse spatial distribution of quarks in the infinite momentum frame as a function of momentum fraction. Ralston and Pire [8], Diehl [9], and Belitsky et al. [10] extended this interpretation to the general case of skewness $\xi \neq 0$. The light-cone wave function representation by Brodsky et al. [11] allows GPDs to be interpreted as interference terms of wave functions for different parton configurations in a hadron.

These concepts stimulated an intense experimental effort in DVCS. The H1 [12,13] and ZEUS [14] Collaborations measured the cross section for $x_{bj} \approx 10^{-3}$. The HERMES Collaboration measured relative beam helicity [15] and beam-charge asymmetries [16,17]. Relative beam helicity [18] and longitudinal target [19] asymmetries were measured at the Thomas Jefferson National Accelerator Facility (JLab) by the CLAS Collaboration.

Extracting GPDs from DVCS requires the fundamental demonstration that DVCS is well described by the twist-2 diagram of Fig. 1 at finite $Q^2$. This Letter reports the first strong evidence of this cornerstone hypothesis, necessary to validate all previous and future GPD measurements using DVCS. We present the determination of the cross section of the $ep \to ep \gamma$ reaction for positive and negative electron helicity in the kinematics of Table I.

The E00-110 [20] experiment ran in Hall A [21] at JLab. The 5.75 GeV electron beam was incident on a 15 cm liquid $H_2$ target. Our typical luminosity was $10^{33}$/cm$^2$/s with 76% beam polarization. We detected scattered electrons in one high resolution spectrometer (HRS). Photons above a 1 GeV energy threshold (and $\gamma \gamma$ coincidences from $\pi^0$ decay) were detected in a 11 x 12 array of 3 x 3 x 18.6 cm$^3$ PbF$_2$ crystals, whose front face was located 110 cm from the target center. We calibrated the PbF$_2$ array by coincident elastic $H(e, e'_{\text{Cals}}p_{\text{HRS}})$ data. With (elastic) $k' = 4.2$ GeV/c, we obtain a PbF$_2$ resolution of 2.4% in energy and 2 mm in transverse position (one-$\sigma$). The calibration was monitored by reconstruction of the $\pi^0 \to \gamma \gamma$ mass from $H(e, e' \pi^0)X$ events.

We present in Fig. 2 the missing mass squared obtained for $H(e, e'\gamma)X$ events, with coincident electron-photon detection. After subtraction of an accidental coincidence sample, we have the following competing channels in addition to $H(e, e'\gamma)p: ep \to e \pi^0 p$, $ep \to e \pi^0 N\pi$, $ep \to e\gamma N\pi$, $ep \to e\gamma N\pi\pi\ldots$. From symmetric (lab-frame) $\pi^0$ decay, we obtain a high statistics sample of $H(e, e'\pi^0)X'$ events, with two photon clusters in the PbF$_2$ calorimeter. From these events, we determine the statistical sample of (asymmetric) $H(e, e'\gamma)\gamma X'$ events that must be present in our $H(e, e'\gamma)X$ data. The solid $M_X^2$ spectrum displayed in Fig. 2 was obtained after subtracting this $\pi^0$ yield from the total (stars) distribution. This is a 14% average subtraction in the exclusive window defined by $M_X^2$ cut in Fig. 2. Depending on the bin in $\phi_{\gamma \gamma}$ and $t$, this subtraction varies from 6% to 29%. After our $\pi^0$ subtraction, the only remaining channels, of type $H(e, e'\gamma)N\pi$, $N\pi\pi$, etc. are kinematically constrained to $M_X^2 > (M + m_{\pi})^2$. This is the value ($M_X^2$ cut in Fig. 2) we chose for truncating our integration. Resolution effects can cause the inclusive channels to contribute below this cut. To evaluate this possible contamination, we used an additional proton array (PA) of 100 plastic scintillators. The PA subtended a solid angle (relative to the nominal direction of the $q$ vector) of $18^\circ < \theta_{\gamma \gamma} < 38^\circ$ and $45^\circ < \phi_{\gamma \gamma} = 180^\circ - \phi_{\gamma \gamma} < 315^\circ$, arranged in 5 rings of 20 detectors.

For $H(e, e'\gamma)X$ events near the exclusive region, we can predict which block in the PA should have a signal from a proton from an exclusive $H(e, e'\gamma p)$ event. Open crosses
show the $X = (p + y)$ missing mass squared distribution for $H(e, e'\gamma)p$ events in the predicted PA block, with a signal above an effective threshold 30 MeV. Squares show our inclusive yield, obtained by subtracting the normalized triple coincidence yield from the $H(e, e'\gamma)X$ yield. The dotted curve shows our simulated $H(e, e'\gamma)p$ spectrum, including radiative and resolution effects, normalized to fit the data for $M_X^2 < M^2$. Triangles show the estimated inclusive yield obtained by subtracting the simulation from the data. Squares and triangles are in good agreement, and show that our exclusive yield has less than 3% contamination from inclusive processes.

To order twist-3 the DVCS helicity-dependent ($d\Sigma$) and helicity-independent ($d\sigma$) cross sections are [22]:

$$d\Sigma \over d^3\Phi = \frac{1}{2} \left[ \frac{d^3\sigma^+}{d^3\Phi} - \frac{d^3\sigma^-}{d^3\Phi} \right]$$

$$= d^3\Sigma([DVCS]^2) + \sin(\phi_{\gamma\gamma}) \Gamma_{11}^{\text{Im}} \text{Im}[C^I(\mathcal{F})]$$

$$- \sin(2\phi_{\gamma\gamma}) \Gamma_{22}^{\text{Re}} \text{Im}[C^I(\mathcal{F}^{\text{eff}})], \quad (1)$$

$$d\sigma \over d^3\Phi = \frac{1}{2} \left[ \frac{d^3\sigma^+}{d^3\Phi} + \frac{d^3\sigma^-}{d^3\Phi} \right]$$

$$= d^3\sigma([DVCS]^2) + d^3\sigma([BH]^2) + \Gamma_{00}^{\text{Re}} \text{Re}[C^I$$

$$+ \Delta C^I(\mathcal{F}) + \Gamma_{00}^{\text{Re}} \text{Re}[C^I(\mathcal{F})]$$

$$- \cos(\phi_{\gamma\gamma}) \Gamma_{22}^{\text{Re}} \text{Im}[C^I(\mathcal{F})]$$

$$+ \cos(2\phi_{\gamma\gamma}) \Gamma_{22}^{\text{Re}} \text{Im}[C^I(\mathcal{F}^{\text{eff}})], \quad (2)$$

where $d^3\Phi = dQ^2dx_B\,dt\,d\phi_{\gamma\gamma}$ and the azimuthal angle $\phi_{\gamma\gamma}$ of the detected photon follows the “Trento Convention” [23]. The $\Gamma_{11}^{\text{Re,Im}}$ are kinematic factors with a $\phi_{\gamma\gamma}$ dependence that arises from the electron propagators of the BH amplitude. The $C^I$ and $\Delta C^I$ angular harmonics depend on the interference of the BH amplitude with the set $\mathcal{F} = \{\mathcal{H}, \mathcal{E}, \mathcal{H}, \mathcal{E}\}$ of twist-2 Compton form factors (CFFs) or the related set $\mathcal{F}^{\text{eff}}$ of effective twist-3 CFFs:

$$C^I(\mathcal{F}) = F_1 \mathcal{H} + \xi G_M \mathcal{H} - \frac{t}{4M^2} F_2 \mathcal{E}, \quad (3)$$

$$C^I(\mathcal{F}^{\text{eff}}) = F_1 \mathcal{H}^{\text{eff}} + \xi G_M \mathcal{H}^{\text{eff}} - \frac{t}{4M^2} F_2 \mathcal{E}^{\text{eff}}, \quad (4)$$

$$[C^I + \Delta C^I](\mathcal{F}) = F_1 \mathcal{H} - \frac{t}{4M^2} F_2 \mathcal{E} - \xi^2 G_M[\mathcal{H} + \mathcal{E}]. \quad (5)$$

$F_1(t), F_2(t),$ and $G_M(t) = F_1(t) + F_2(t)$ are the elastic form factors. CFFs are defined in terms of the GPDs $H_f, E_f, \tilde{H}_f,$ and $\tilde{E}_f,$ defined for each quark flavor $f$. For example, $(f \in \{u, d, s\})$:

$$\mathcal{H}(\xi, t) = \sum_f \frac{e_f}{\xi} \left[ i\pi[H_f(\xi, \xi, t) - H_f(-\xi, \xi, t)] \right. + \mathcal{P} \int_{-1}^{+1} dx \left[ \frac{2x}{\xi^2 - x^2} \right] H_f(x, \xi, t) \right]. \quad (6)$$

Thus, the DVCS helicity-dependent and helicity-independent cross sections provide very distinct and complementary information on GPDs. On one hand, $d\Sigma$ measures the imaginary part of the BH-DVCS interference terms and provides direct access to GPDs at logarithmic QCD evolution). Their $Q^2$ variation measures the potential contamination from higher twists.

The helicity-independent cross section also has a $\cos(3\phi_{\gamma\gamma})$ twist-2 gluon transversity term. We expect this term to be small, and do not include it in our analysis. We neglect the DVCS$^2$ terms in our analysis. Therefore, our results for $\text{Im}[C^I]$ and $\text{Re}[C^I]$ may contain, respectively, twist-3 and twist-2 DVCS$^2$ terms, which enter with similar $\phi_{\gamma\gamma}$ dependence. However, the DVCS$^2$ terms in both $d\sigma$ and $d\Sigma$ are kinematically suppressed by at least an order of magnitude in our kinematics [22], because they are not enhanced by the BH amplitude. In any case, the terms we neglect do not affect the cross sections we extract, which are accurately parametrized, within statistics, by the contributions we included.

Our simulation includes internal bremsstrahlung in the scattering process and external bremsstrahlung and ionization straggling in the target and scattering chamber win-
dows. We include spectrometer resolution and acceptance effects and a full GEANT3 simulation of the detector response to the DVCS photons and protons. The spectrometer acceptance is defined for both the data and simulation by a R-function cut [24]. Radiative corrections for virtual photons and unresolved real photons are applied according to the VCS (BH + Born amplitude) specific prescriptions of Ref. [25]. This results in a global correction factor (independent of $\phi_{\gamma\gamma}$ or helicity) of 0.91 ± 0.02 applied to our experimental yields. Within the quoted uncertainty, this correction is independent of the kinematic setting.

For each ($Q^2$, $x_{Bj}$, $t$) bin, we fit the Re and Im parts (as appropriate) of the harmonics $C_n \in \{C(I)F\}, \{C(I)F^{\text{eff}}\}, \{C(I) + \Delta C(I)F\}$ as independent parameters. In Kin-1 and Kin-2, due to the lower photon energy $E_\gamma$ (Table I), our acceptance, trigger, and readout did not record a comprehensive set of $e p \rightarrow e \pi^0 X$ events. For those events we were able to reconstruct, we found only a few percent contribution to $d\Sigma$, but a larger contribution to $d\sigma$. For Kin-1,2, we only present results on $d\Sigma$. Our systematic errors in the cross-section measurements are dominated by the following contributions: 3% from HRS $\times$ PbF$_3$ acceptance and luminosity; 3% from $H(e,e'\gamma)\gamma X$ ($\pi^0$) background; 2% from radiative corrections; and 3% from inclusive $H(e,e'\gamma)N\pi\ldots$ background. The total, added in quadrature, is 5.6%. The $d\Sigma$ results contain an additional 2% systematic uncertainty from the beam polarization. In order to compute the BH contribution in the $d\sigma$ analysis we used Kelly’s parametrization of form factors [26], which reproduce elastic cross-section world data in our $t$ range with 1% error and 90% C.L.

For one ($Q^2$, $x_{Bj}$, $t$) bin, Fig. 3 shows the helicity-dependent and helicity-independent cross sections, respectively. We notice that the twist-3 terms make only a very small contribution to the cross sections. Note also that $d\sigma$ is much larger than the BH contribution alone, especially from 90° to 270°. This indicates that the relative beam spin asymmetry BSA = $d^4\Sigma/d^4\sigma$ cannot be simply equated to the imaginary part of the BH-DVCS interference divided by the BH cross section. Table II lists the extracted angular harmonics. Figure 4 (left) shows the $Q^2$ dependence of the imaginary angular harmonic $\text{Im}[C(I)F]$ over our full $t$ domain, with $\langle t \rangle = -0.25$ GeV$^2$ ($\langle t \rangle$ varying by ±0.01 GeV$^2$ over Kin 1-3).

The absence of $Q^2$ dependence of $\text{Im}[C(I)F]$ within its 3% statistical uncertainty provides crucial support for the dominance of twist-2 in the DVCS amplitude. Indeed, it sets an upper limit ≤ 10% to twist-4 and higher contributions. $\text{Im}[C(I)F]$ is thereby a direct measurement of a linear combination of GPDs. The two twist-2 angular harmonics extracted from $d\sigma$ determine distinct combinations of GPD integrals, providing most valuable complementary information on GPDs. As noted above, the angular
