Inclusive charged hadron elliptic flow in Au + Au collisions at $\sqrt{s_{NN}} = 7.7–39$ GeV
A systematic study is presented for centrality, transverse momentum ($p_T$), and pseudorapidity ($\eta$) dependence of the inclusive charged hadron elliptic flow ($v_2$) at midrapidity ($|\eta| < 1.0$) in Au + Au collisions at $\sqrt{s_{NN}} = 7.7, 11.5, 19.6, 27,$ and $39 \text{ GeV}$. The results obtained with different methods, including correlations with the event plane reconstructed in a region separated by a large pseudorapidity gap and four-particle cumulants ($v_2[4]$), are presented to investigate nonflow correlations and $v_2$ fluctuations. We observe that the difference between $v_2[2]$ and $v_2[4]$ is smaller at the lower collision energies. Values of $v_2$, scaled by the initial coordinate space eccentricity, $v_2/\varepsilon$, as a function of $p_T$ are larger in more central collisions, suggesting stronger collective flow develops in more central collisions, similar to the results at higher collision energies. These results are compared to measurements at higher energies at the Relativistic Heavy Ion Collider ($\sqrt{s_{NN}} = 62.4$ and 200 GeV) and at the Large Hadron
Collider (Pb + Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV). The $v_2(p_T)$ values for fixed $p_T$ rise with increasing collision energy within the $p_T$ range studied ($<2$ GeV/$c$). A comparison to viscous hydrodynamic simulations is made to potentially help understand the energy dependence of $v_2(p_T)$. We also compare the $v_2$ results to UrQMD and AMPT transport model calculations, and physics implications on the dominance of partonic versus hadronic phases in the system created at beam energy scan energies are discussed.

**I. INTRODUCTION**

Azimuthal anisotropies of particle distributions relative to the reaction plane (plane subtended by the impact parameter and beam direction) in high-energy heavy-ion collisions have been used to characterize the collision dynamics [1–3]. In a picture of hydrodynamic expansion of the system formed in the collisions, these anisotropies are expected to arise owing to initial pressure gradients and subsequent interactions of the constituents [4,5]. Specifically, differential measurements [6–19] of azimuthal anisotropy have been found to be sensitive to (a) the equation of state (EOS), (b) thermalization, (c) transport coefficients of the medium, and (d) initial conditions in the heavy-ion collisions. Hence, it is important to study the dependence of azimuthal anisotropy as a function of several variables, for example center-of-mass energy ($\sqrt{s_{NN}}$), collision centrality, transverse momentum ($p_T$), and pseudorapidity ($\eta$).

Recently, a beam-energy scan (BES) program has begun at RHIC to study the QCD phase diagram [20]. The BES program extends the baryonic chemical potential ($\mu_B$) reach of RHIC from 20 MeV to about 400 MeV [21,22]. The baryon chemical potential decreases with the decrease in the beam energy while the chemical freeze-out temperature increases with increase in beam energy [23]. This allows one to study azimuthal anisotropy at midrapidity with varying net-baryon densities. Lattice QCD calculations suggest that the quark-hadron transition is a crossover for high-temperature ($T$) systems with small $\mu_B$ or high $\sqrt{s_{NN}}$ [24]. Several model calculations suggest that at larger values of $\mu_B$ or lower $\sqrt{s_{NN}}$ the transition is expected to be first order [25–27]. Theoretical calculations suggest a nonmonotonic behavior of $v_2$ could be observed around this “softest point of the EOS” [28].

The softest point of the EOS is usually referred to as the temperature/time during which the velocity of sound has a minimum value (or reduction in the pressure of the system) during the evolution. Nonmonotonic variation of azimuthal anisotropy as a function of collision centrality and $\sqrt{s_{NN}}$ could indicate the softest point of the EOS in heavy-ion reactions [29]. Further, it has been argued that the observation of saturation of differential azimuthal anisotropies $v_2(p_T)$ of charged hadrons in Au + Au collisions in the $\sqrt{s_{NN}}$ range of 62.4–200 GeV is a signature of a mixed phase [15]. The new data presented in this paper shows to what extent such a saturation effect is observed.

Several analysis methods for $v_2$ have been proposed [30–34]. These are found to be sensitive in varying degrees to nonflow contributions (e.g., correlations owing to jets, resonances, etc.) and flow fluctuations. $v_2$ measurements from various methods have been judiciously used to constrain these contributions, in addition to providing estimates of systematic errors associated with the measurements [35]. This is particularly useful for interpreting results of identified hadron $v_2$ values where, owing to limitations of event statistics, it is not possible to use all methods for $v_2$ analysis. The measurements over a range of energies may provide insights to the evolution of nonflow and flow fluctuations as a function of collision energy.

Inclusive charged hadron elliptic flow measurements at top RHIC energies have been one of the most widely studied observables from the theoretical perspective. It has been shown that transport models, which provide a microscopic description of the early and late nonequilibrium stages of the system, significantly underpredict $v_2$ at top RHIC energies, while the inclusion of partonic effects provides a more satisfactory explanation [36]. The new data discussed here will provide an opportunity to study the contribution of partonic matter and hadronic matter to the $v_2$ measurements as a function of $\sqrt{s_{NN}}$ or $(T, \mu_B)$ by comparisons with models.

In this paper we present measurements of the second harmonic azimuthal anisotropy using data taken in the BES program from $\sqrt{s_{NN}} = 7.7$ to 39 GeV. We discuss the detectors used in the analysis, data selections, and methods used to determine inclusive charged hadron $v_2$ in Secs. II and III. Section IV gives $v_2$ results for inclusive charged hadrons from different analysis methods. We discuss the centrality, $p_T$, and $\sqrt{s_{NN}}$ dependence of $v_2$ in Sec. V and compare to calculations from transport models. Finally, a summary of the analysis is presented in Sec. VI.

**II. EXPERIMENTS AND DATA SETS**

A. STAR detector

The results presented here are based on data collected during the 10th and 11th RHIC runs (2010 and 2011) with the STAR detector using minimum-bias triggers (requiring a combination of signals from the beam-beam counters (BBCs) [37], zero-degree calorimeters (ZDCs) [38], and vertex position detectors (VPDs) [39]). For the 7.7- and 11.5-GeV data, at least one hit in the full barrel time-of-flight detector [40] was required to further reduce the background. The main time projection chamber (TPC) [41] and two forward time projection chambers (FTPCs) [42] were used for particle tracking in the central region ($|\eta| < 1.0$) and forward regions ($2.5 < |\eta| < 4.0$), respectively. Both the TPC and the FTPCs provided azimuthal acceptance over $2\pi$. The BBC detector subsystem consists of two detectors mounted around the beam pipe, each located outside the STAR magnet pole tip at opposite ends of the TPC approximately 375 cm from the center of the nominal interaction point. Each BBC detector consists of hexagonal scintillator tiles arranged in four concentric rings...
that provided full azimuthal coverage. The inner tiles of the BBCs, with a pseudorapidity range of \(3.8 < |\eta| < 5.2\) were used to reconstruct the event plane in one elliptic flow analysis.

**B. Event and track selection**

Events for analysis are selected based on collision vertex positions within 2 cm of the beam axis to reduce contributions from beam-gas and beam-pipe (at a radius of 4 cm) interactions, and within a limited distance from the center of the detector along the beam direction (±70 cm for the 7.7-GeV data set, ±50 cm for the 11.5-GeV data set, and ±40 cm for the 19.6-, 27-, and 39-GeV data sets). These values are chosen to reduce systematics owing to variance in detector performance over \(|\eta| < 1.0\) while retaining sufficient statistics. After quality cuts, about 4 \(\times 10^6\) 0%–80% central events remain for 7.7 GeV, 11 \(\times 10^6\) for 11.5 GeV, 20 \(\times 10^6\) for 19.6 GeV, 40 \(\times 10^6\) for 27 GeV, and 120 \(\times 10^6\) for 39 GeV data sets. The results from more peripheral collisions are not presented owing to trigger inefficiencies at low multiplicity. The centrality was defined using the number of charged tracks with quality cuts similar to those in Ref. [12]. The details of the centrality determination is discussed in Part C of this section. The 0%–80% central events for \(v_2\) analysis of charged hadrons are divided into nine centrality bins: 0%–5%, 5%–10%, 10%–20%, 20%–30%, 30%–40%, 40%–50%, 50%–60%, 60%–70%, and 70%–80%.

A variety of track quality cuts are used to select good charged particle tracks reconstructed using information from the TPC or FTPCs. The distance of closest approach (DCA) of the track to the primary vertex is taken to be less than 2 cm. We require that the TPC and FTPCs have a number of fit points used for reconstruction of the tracks to be >15 and >5, respectively. For the TPC and FTPCs the ratio of the number of fit points to maximum possible hits is >0.52. An additional transverse momentum cut (0.2 < \(p_T\) < 2 GeV/c) is applied to the charged tracks for the TPC and FTPC event-plane determination.

**C. Centrality determination**

The centrality classes are defined based on the uncorrected charged-particle multiplicity \(N_{ch}^{raw}\) in the TPC for pseudorapidity \(|\eta| < 0.5\) and full azimuth.

Figure 1 shows the \(N_{ch}^{raw}\) distribution for charged particles from the data at \(\sqrt{s_{NN}} = 7.7, 11.5, 19.6, 27,\) and 39 GeV compared to those from Monte Carlo (MC) Glauber simulations. The detailed procedures to obtain the simulated multiplicity are similar to that described in Ref. [43]. A two-component model [44] is used to calculate the simulated multiplicity distribution given by

\[
\frac{dN_{ch}}{d\eta} \bigg|_{\eta=0} = n_{pp} \left[ (1-x) \frac{N_{part}}{2} + x N_{coll} \right],
\]

where \(N_{part}\) is the number of participant nucleons and \(N_{coll}\) is the number of binary nucleon-nucleon collisions in the simulations. The fitting parameter \(n_{pp}\) is the average multiplicity per unit of pseudorapidity in minimum-bias \(p + p\) collisions and \(x\) is the fraction of production from the hard component.

The inelastic nucleon-nucleon cross section \(\sigma_{N_N}^{inel}\) is extracted from fitting the results of available data for total and elastic \(p + p\) cross sections from the Particle Data Group [45]. The \(x\) value is fixed at 0.12 ± 0.02 based on the linear interpolation of the PHOBOS results at \(\sqrt{s_{NN}} = 19.6\) and 200 GeV [46]. Systematic errors on \(n_{pp}\) are evaluated by varying both \(n_{pp}\) and \(x\) within the quoted \(x\) uncertainty to determine the minimum \(\chi^2\) to describe the data. Because the \(n_{pp}\) and \(x\) are anticorrelated, lower (higher) \(n_{pp}\) is used for higher (lower) \(x\) for systematic error evaluations on \(N_{part}\). Table I summarizes the parameters in the two-component model and \(\sigma_{N_N}^{inel}\) in the MC Glauber simulations. The event-by-event multiplicity fluctuations are included using negative binomial distributions [43]. The centrality classes are defined by the fractions of geometrical cross section from the simulated multiplicity distributions. For each centrality bin, average quantities are calculated in the MC Glauber simulations for \(\langle N_{part}\rangle, \langle N_{coll}\rangle, \) reaction plane eccentricity \(\epsilon_{RP}\), participant eccentricity \(\epsilon_{part}\), root-mean-square participant eccentricity \(\epsilon_{part}^2\), and transverse area \(S_{part}\). Eccentricity and transverse area are defined by

\[
\epsilon_{RP} = \frac{\sigma_y^2 + \sigma_y^2}{\sigma_x^2 + \sigma_y^2},
\]

**TABLE I.** Summary of \(n_{pp}\) and \(\sigma_{N_N}^{inel}\) with systematic uncertainties at \(\sqrt{s_{NN}} = 7.7, 11.5, 19.6, 27,\) and 39 GeV. \(x\) is set to 0.12 ± 0.02 for all collision energies.

For any Fourier harmonic, particle of interest, which can be done for each harmonic, the event plane determined from the full event minus the systematic uncertainties. Table II summarizes the centrality fluctuations owing to finite number of particles, one has to correct for this smearing by dividing the observed correlation by the event-plane resolution [the denominator in Eq. (11)], which is necessary [47,48].

\[
\varepsilon_{\text{part}} = \frac{(\sigma_y^2 - \sigma_x^2)^2 + 4\sigma_{xy}^2}{\sigma_x^2 + \sigma_y^2}, \quad \varepsilon_{\text{part}}[2] = \sqrt{\varepsilon_{\text{part}}^2},
\]

\[
S_{\text{part}} = \pi \sigma_x^2\sigma_y^2 - \sigma_{xy}^2,
\]

\[
\sigma_x^2 = \langle x^2 \rangle - \langle x \rangle^2, \quad \sigma_y^2 = \langle y^2 \rangle - \langle y \rangle^2, \quad \sigma_{xy} = \langle xy \rangle - \langle x \rangle \langle y \rangle,
\]

where the curly brackets denote the average over all participants per event and \( x \) and \( y \) are the positions of participant nucleons. Systematic uncertainties on those quantities are evaluated by varying the input parameters in the MC Glauber model. The quoted errors are the quadratic sum of the individual systematic uncertainties. Table II summarizes the centrality classes as well as the results obtained by MC Glauber simulations at the five energies.

### III. ELLIPTIC FLOW METHODS

#### A. The event-plane method

The event-plane method [30] correlates each particle with the event plane determined from the full event minus the particle of interest, which can be done for each harmonic. For any Fourier harmonic, \( n \), the event flow vector (\( Q_n \)) and the event-plane angle (\( \Psi_n \)) are defined by [30]

\[
Q_n \cos n \Psi_n = Q_{nx} = \sum_i w_i \cos n \phi_i, \quad Q_n \sin n \Psi_n = Q_{ny} = \sum_i w_i \sin n \phi_i, \quad \Psi_n = \left( \frac{\tan^{-1} Q_{ny}}{Q_{nx}} \right)/n,
\]

where sums extend over all particles \( i \) used in the event-plane calculation, and \( \phi_i \) and \( w_i \) are the laboratory azimuthal angle and the weight for the \( i \)th particle, respectively. The reaction plane azimuthal distribution should be isotropic or flat in the laboratory frame if the detectors have ideal acceptance. Because the detectors usually have nonuniform acceptance, a procedure for flattening the laboratory event-plane distribution is necessary [47,48].

As shown in Eq. (10), the observed \( v_2 \) is calculated with respect to the reconstructed event-plane angle \( \Psi_n \), where \( n \) equals 2 when we use the second harmonic event plane and \( n \) equals 1 when we use the first harmonic event plane:

\[
v_2^{\text{obs}} = \langle \cos [2(\phi - \Psi_n)] \rangle.
\]

The angular brackets indicate an average over all particles in all events. However, tracks used for the \( v_2 \) calculation are excluded from the calculation of the flow vector to remove self-correlation effects. Because the estimated reaction plane fluctuates owing to finite number of particles, one has to correct for this smearing by dividing the observed correlation by the event-plane resolution [the denominator in Eq. (11)], which is

the correlation of the event plane with the reaction plane:

\[
v_2 = \frac{v_2^{\text{obs}}}{\langle \cos [2(\Psi_n - \Psi_r)] \rangle}.
\]

Because the reaction plane is unknown, the denominator in Eq. (11) could not be calculated directly. As shown in Eq. (12), we estimate the event-plane resolution by the correlation between the azimuthal angles of two subset groups of tracks, called subevents \( A \) and \( B \). In Eq. (12) \( C \) is a factor calculated from the known multiplicity dependence of the resolution [30]:

\[
\langle \cos [2(\Psi_n - \Psi_r)] \rangle = C \sqrt{\langle \cos [2(\Psi_n^A - \Psi_n^B)] \rangle}.
\]

Random subevents are used for TPC event plane, while pseudorapidity subevents are used for FTPC/BBC event plane.

1. **TPC event plane**

The TPC event plane means the event plane reconstructed from tracks recorded by the TPC. For this event plane the \( \phi \) weight method is an effective way to flatten the azimuthal distribution for removing detector acceptance bias. These weights are generated by inverting the \( \phi \) distributions of detected tracks for a large event sample. The \( \phi \) weights are folded into the weight \( w_i \) in Eqs. (7) and (8).

The recentering correction [47,48] is another method to calibrate the event plane. In this method, one subtracts from the \( Q \) vector of each event the \( Q \) vector averaged over many events. For both the \( \phi \) weight and recentering methods, the corrections are applied in each centrality bin, in two bins of the primary vertex position along the longitudinal beam direction (\( V_z \)), and in two bins for positive/negative pseudorapidity. These corrections are determined as a function of data collection time. The difference in the effects on \( v_2 \) from the different flattening techniques is negligible.

2. **FTPC event plane**

Forward-going tracks reconstructed in the two FTPCs can also be used to determine the event plane. However, large acceptance losses from hardware faults caused significant gaps in the azimuthal angle distribution of these tracks, preventing use of the \( \phi \) weight method because of the inability to define \( \phi \) weights in regions of zero acceptance. Thus, only the recentering method is used for the FTPC.

3. **BBC event plane**

In this method the first-order event plane is reconstructed using particle trajectories determined from hits in the BBC detectors. In this case, \( \phi_i \) denotes the fixed azimuthal angle of the center of the \( i \)th BBC tile in Eqs. (7) and (8), and \( w_i \) is the fraction of BBC-observed energy deposition recorded in tile \( i \):

\[
w_i = \frac{A_i}{\sum A_i}.
\]
TABLE II. Summary of centrality bins, average number of participants \((N_{\text{part}})\), number of binary collisions \((N_{\text{coll}})\), reaction plane eccentricity \((\varepsilon_{\text{RP}})\), participant eccentricity \((\varepsilon_{\text{part}})\), root-mean-square the participant eccentricity \(\varepsilon_{\text{part}}[2]\), and transverse area \((S_{\text{part}})\) from MC Glauber simulations at \(\sqrt{s_{\text{NN}}} = 7.7, 11.5, 19.6, 27,\) and \(39\) GeV. The errors are systematic uncertainties.

\(\varepsilon_{\text{part}}[2]\) values range from 0.10 to 0.46, with a maximum of 0.46 at \(\sqrt{s_{\text{NN}}} = 11.5\) GeV for \(20-30\) centrality. The uncertainties are given as systematic uncertainties.
The BBC event plane obtained from one BBC detector is called a subevent. A combination of the subevent-plane vectors for both BBC detectors provides the full event plane,

\[ v_2\{\text{BBC}\} = \frac{\langle \cos(2(\phi - \Psi)) \rangle}{C\sqrt{\cos[2(\Psi_1^\Delta - \Psi_1^\Delta)]}}, \]

where \(C\) is the constant in Eq. (12). \(\Psi_1^\Delta\) and \(\Psi_2^\Delta\) are subevent-plane angles from each BBC detector and \(\Psi_1\) is the full event-plane angle from both subevents combined.

The detector acceptance bias is removed by applying the shift method [48]. Equation (15) shows the formula for the shift correction. The averages in Eq. (15) are taken from a large sample of events. In this analysis, the correction is done up to the 20th harmonic. The distributions of \(\Psi_1^\Delta\) and \(\Psi_2^\Delta\) are separately flattened and then the full-event-plane distribution is flattened. Accordingly, the observed \(v_2\) and resolution are calculated using the shifted (sub)event-plane azimuthal angles:

\[ \Psi' = \Psi + \sum_n \frac{1}{n} \left[ \langle \sin(2n\Psi) \rangle \cos(2n\Psi) \right. \]
\[ \left. + \langle \cos(2n\Psi) \rangle \sin(2n\Psi) \right]. \]

More details for the BBC event plane have been described in Ref. [49].

\section{The \(\eta\) subevent method}

The \(\eta\) subevent method is similar to the event-plane method, except one defines the flow vector for each particle based on particles measured in the opposite hemisphere in pseudorapidity:

\[ v_2\{\text{EtaSubs}\} = \frac{\langle \cos(2(\phi_{\eta, \Psi_2}) - \Psi_{\eta, \Psi_2}) \rangle}{\sqrt{\cos[2(\Psi_{2n, \Psi_2} - \Psi_{2n, \Psi_2})]}}. \]

Here \(v_2\{\text{EtaSubs}\}\) denotes the results of the \(\eta\) subevent method and \(\Psi_{2n, \Psi_2}\) is the second harmonic event-plane angle determined by particles with positive (negative) pseudorapidity. An \(\eta\) gap of \(|\eta| < 0.075\) is used between negative (positive) \(\eta\) subevents to reduce nonflow correlations between the two ensembles.

\section{The cumulant method}

The advantage of the cumulant method is that the multiparticle cumulant is a higher-order multiparticle correlation formalism which removes the contribution of nonflow correlations from lower-order correlations [32,33]. The measured two-particle correlations can be expressed with flow and nonflow components:

\[ \langle e^{in(\phi_1 - \phi_2)} \rangle = \langle e^{in(\phi_1 - \Psi_1)} \rangle \langle e^{in(\Psi_1 - \phi_2)} \rangle + \delta_n = v_n^2 + \delta_n. \]

Here \(n\) is the harmonic number and \(\delta_n\) denotes the nonflow contribution. The average should be taken for all pairs of particles in a certain rapidity and transverse momentum region and for all events of a data sample. The measured four-particle correlations can be expressed as

\[ \langle e^{in(\phi_1 + \phi_2 - \phi_3 - \phi_4)} \rangle = v_n^4 + 2 \times \langle e^{in(\phi_1 - \Psi_1)} \rangle v_n^2 \delta_n + 2 \delta_n^2. \]

Thus, the flow contribution can be obtained by subtracting the two-particle correlation from the four-particle correlation,

\[ \langle e^{in(\phi_1 + \phi_2 - \phi_3 - \phi_4)} \rangle = \langle e^{in(\phi_1 + \phi_2 - \phi_3)} \rangle - 2\langle e^{in(\phi_1 - \phi_2)} \rangle^2 \]

where \(\langle \cdots \rangle\) is used for the cumulant. The cumulant of order two is just \(\langle e^{in(\phi_1 - \phi_2)} \rangle\).

\subsection{The cumulant method with generating function}

The GF-cumulant method is computed from a generating function [33]:

\[ G_n(z) = \prod_{j=1}^{M} \left[ 1 + \frac{w_j}{M} (z^* e^{in\phi_1} + ze^{-in\phi_1}) \right]. \]

Here \(z\) is an arbitrary complex number, \(z^*\) denotes its complex conjugate, \(M\) denotes the multiplicity in each event, and \(w_j\) is the weight (transverse momentum, rapidity, etc.) used in the analysis. The eventwise averaged generating function then can be expanded in powers of \(z\) and \(z^*\), where the coefficients of expansion yield the correlations of interest:

\[ \langle G_n(z) \rangle = 1 + z \langle e^{-in\phi_1} \rangle + z^* \langle e^{in\phi_1} \rangle + \frac{M - 1}{M} \left( \frac{z^2}{2} \langle e^{in(\phi_1 + \phi_2)} \rangle + \frac{z^*}{2} \langle e^{in(\phi_1 - \phi_2)} \rangle \right) + \cdots. \]

These correlations can be used to construct the cumulants. More details for the analysis of STAR data have been described in Ref. [10].

\subsection{The \(Q\)-cumulants method}

The \(Q\)-cumulants method [50] is a recent method to calculate cumulants without using nested loops over tracks and without generating functions [33]. The advantage is that it provides fast (one loop over data) and exact nonbiased (no approximations and no interference between different harmonics) estimates of the correlators compared to the generating function cumulants. The cumulants are expressed in terms of the moments of the magnitude of the corresponding flow vector \(Q_n\)

\[ Q_n = \sum_{i=1}^{M} e^{in\phi_i}. \]

The single-event average two- and four-particle azimuthal correlations can be then formulated as

\[ \langle v_2 \rangle = \frac{|Q_2|}{M(M-1)} \]
\[ \langle Q_2 \rangle = \frac{|Q_2|^2 + |Q_{2n}|^2 - 2\text{Re}[Q_{2n} Q_{2n}]M(M-1)(M-2)(M-3)}{M(M-1)(M-2)(M-3)} \]

\[ \langle v_4 \rangle = \frac{2|Q_4| - 2\text{Re}[Q_{2n} Q_{2n}]M(M-1)(M-2)(M-3)}{M(M-1)(M-2)(M-3)} \]
The average over all events can be performed as
\[ \langle \langle \langle 2 \rangle \rangle \rangle = \frac{\sum_{i=1}^{\text{events}} W(2)_i \langle f(2)_i \rangle}{\sum_{i=1}^{\text{events}} W(2)_i}, \tag{25} \]
\[ \langle \langle 4 \rangle \rangle = \frac{\sum_{i=1}^{\text{events}} W(4)_i \langle f(4)_i \rangle}{\sum_{i=1}^{\text{events}} W(4)_i}, \tag{26} \]
while the weights are the number of two- and four-particle combinations:
\[ W(2) = M(M-1), \tag{27} \]
\[ W(4) = M(M-1)(M-2)(M-3). \tag{28} \]
Choosing the multiplicity weights above can make the final multiparticle azimuthal correlations free of multiplicity fluctuations [51]. However, one can also use unit weights treating events with different multiplicity equally. The two- and four-particle cumulants without detector bias then can be formulated as
\[ c_n[2] = \langle \langle 2 \rangle \rangle, \tag{29} \]
\[ c_n[4] = \langle \langle 4 \rangle \rangle - 2 \times \langle \langle 2 \rangle \rangle^2. \tag{30} \]
The reference flow (e.g., integrated over \( p_T \)) can be estimated both from two- and four-particle cumulants:
\[ v_n[2] = \sqrt{c_n[2]}, \tag{31} \]
\[ v_n[4] = \sqrt{-c_n[4]}. \tag{32} \]

Once the reference flow is estimated, we proceed to the calculation of differential flow (e.g., as a function of \( p_T \)) of the particle of interest (POI), which needs another two vectors \( p \) and \( q \). Particles used to estimate reference flow are called reference particles (REPs). For particles labeled as POI,
\[ p_n = \sum_{i=1}^{m_p} e^{i n \psi_i} \tag{33} \]
For particles labeled as both POI and REP,
\[ q_n = \sum_{i=1}^{m_p} e^{i n \psi_i} \tag{34} \]
Then the reduced single-event average two- and four-particle correlations are
\[ \langle \langle 2' \rangle \rangle = \frac{p_n Q_n^* - m_q}{m_p M - m_q}, \tag{35} \]
\[ \langle \langle 4' \rangle \rangle = \left[ p_n Q_n Q_n^* Q_n^* - q_{2n} Q_n Q_n^* - p_n Q_n Q_n^* Q_n^* - 2 M p_n Q_n^* Q_n^* + 2 m_q Q_n^* Q_n^* + 2 m_q M - 6 m_q \right] / (m_p M - 3 m_q)(M - 1)(M - 2). \tag{36} \]

The event average can be obtained as follows:
\[ \langle \langle 2' \rangle \rangle = \frac{\sum_{i=1}^{\text{events}} W(2)_i \langle f(2)_i \rangle}{\sum_{i=1}^{\text{events}} W(2)_i}, \tag{37} \]
\[ \langle \langle 4' \rangle \rangle = \frac{\sum_{i=1}^{\text{events}} W(4)_i \langle f(4)_i \rangle}{\sum_{i=1}^{\text{events}} W(4)_i}. \tag{38} \]

Multiplicity weights are
\[ w(2) = m_p M - m_q, \tag{39} \]
\[ w(4) = (m_p M - m_q)(M - 1)(M - 2). \tag{40} \]
The two- and four-particle differential cumulants without detector bias are given by
\[ d_n[2] = \langle \langle 2' \rangle \rangle, \tag{41} \]
\[ d_n[4] = \langle \langle 4' \rangle \rangle - 2 \times \langle \langle 2' \rangle \rangle \langle \langle 2 \rangle \rangle. \tag{42} \]

Equations for the case of detectors without uniform acceptance can be found in Ref. [50]. Estimations of differential flow are expressed as
\[ v_n'[2] = \frac{d_n[2]}{\sqrt{c_n[2]}} \tag{43} \]
\[ v_n'[4] = \frac{d_n[4]}{-c_n[2]^{3/2}}. \tag{44} \]

IV. RESULTS

A. The event-plane resolution

To investigate the nonflow correlations and \( v_2 \) fluctuations of the \( v_2 \) measurements, the event planes from different detectors and the cumulant method are used in the analysis. The event planes are determined from the TPC in the midrapidity region, and the FTPC/BBC at forward rapidity. The \( \eta \) gap between FTPC/BBC to TPC could reduce the nonflow contribution in the \( v_2 \) measurement [13]. Figure 2 shows the

![FIG. 2. (Color online) The event-plane resolutions for Au + Au collisions at \( \sqrt{s_{NN}} = 7.7, 11.5, 19.6, 27 \) and 39 GeV as a function of collision centrality. Panel (a) shows the resolution of the second harmonic event plane from the TPC (|\( \eta \)| < 1). Panel (b) shows the resolution for second harmonic event plane from the FTPCs (2.5 < |\( \eta \)| < 4.0) for 39 GeV and second harmonic event-plane resolution correction using the first-order event plane from the BBCs (3.8 < |\( \eta \)| < 5.2) for 7.7, 11.5, 19.6, and 27 GeV.](http://example.com/fig2.png)
event-plane resolution from TPC [panel (a)] and BBC (FTPC) [panel (b)]. The resolution of the TPC second harmonic event plane increases as the collision energy increases, as the resolution depends on the multiplicity and the \( v_2 \) signal [30]. Owing to limited statistics, the FTPC event plane is used only for the 39-GeV data set where the BBC event plane cannot be used because of the poor resolution. The resolution of the FTPC event plane is about four times lower than the TPC event plane. The BBC is used to determine the event plane. The BBC is based on the first harmonic, as the \( v_1 \) signal is significant in the rapidity region covered by the BBC. The qualitatively different centrality dependence of the FTPC and BBC event-plane resolutions is because of the different centrality dependence of \( v_1 \) and \( v_2 \).

### B. Method comparison

The comparison of \( v_2 \) as a function of \( p_T \) between the GF-cumulant and \( Q \)-cumulant methods is shown in Fig. 3 for six collision centralities in Au + Au collisions at \( \sqrt{s_{NN}} = 39 \) GeV. The GF-cumulant and \( Q \)-cumulant methods agree within 5% at all five collision energies. Compared to the GF-cumulant method, the recently developed \( Q \) cumulant is the exact cumulant method [50]. The observation of consistency between the two methods at BES energies implies that the GF cumulant is a good approximation. The cumulant method (GF cumulant or \( Q \) cumulant) used in the analysis does not cause difference in the comparison with other experimental results and theoretical calculations. To be consistent with the previous STAR results, we hereafter show only results from the GF-cumulant method.

Other method comparisons are shown in Figs. 4 and 5 for inclusive charged hadrons in Au + Au collisions at \( \sqrt{s_{NN}} = 7.7 \) GeV (a1), 11.5 GeV (b1), 19.6 GeV (c1), 27 GeV (d1), and 39 GeV (e1). As the \( v_2 \) measurements from various methods are obtained using charged tracks recorded at midrapidity (|\( \eta \)| < 1), the statistical errors on the results from the different \( v_2 \) methods are thus correlated. The conclusions on the differences in \( v_2 \) values from different methods are based on the systematic trends observed for the corresponding ratios with respect to \( v_2 \). Figure 4 shows \( v_2 \) integrated over 0 < \( p_T < 2.0 \) GeV/c and |\( \eta \)| < 1 versus centrality. For comparison purposes, the integrated \( v_2 \) values for all methods are divided by the values of the two-particle cumulant method (\( v_2 \)) and plotted in panels (a2) through (e2). The results of the four-particle cumulants are systematically lower than the other methods, except for \( v_2 \) (FTPC/BBC). The difference is about 10%–20% in 39, 27, and 19.6 GeV, 10%–15% in 11.5 GeV, and 5%–10% in 7.7 GeV. The \( \eta \) subevent values for peripheral collisions (50%–60% to 70%–80%) drop below the two-particle and TPC event-plane results, indicating the \( \eta \) subevent method could reduce some nonflow fluctuations.

---

**FIG. 3.** (Color online) The comparison of \( v_2 \) as a function of \( p_T \) between GF-cumulant (open symbols) and \( Q \)-cumulant (solid symbols) methods in Au + Au collisions at \( \sqrt{s_{NN}} = 39 \) GeV. \( v_2 \) fails in most central (0%–5%) collisions owing to the small values of \( v_2 \) and large \( v_2 \) fluctuations.

**FIG. 4.** (Color online) The \( p_T \) (>0.2 GeV/c) and \( \eta \) (|\( \eta \)| < 1) integrated \( v_2 \) as a function of collision centrality for Au + Au collisions at \( \sqrt{s_{NN}} = 7.7 \) GeV (a1), 11.5 GeV (b1), 19.6 GeV (c1), 27 GeV (d1), and 39 GeV (e1). The results in the top panels are presented for several methods of obtaining \( v_2 \). The bottom panels show the ratio of \( v_2 \) obtained using the various techniques, with respect to \( v_2 \). The error bars shown are statistical.
correlations for peripheral collisions. Nonflow correlations are defined as correlations not related to the reaction plane. The dominant nonflow correlations originating from two-particle correlations (such as HBT correlations, resonance decay) scale as $1/N$ [30], where $N$ is the multiplicity of particles used to determine the event plane. Thus, the nonflow contribution is larger in peripheral collisions. In midcentral particles used to determine the event plane. Thus, the nonflow correlations and discussed in the text. The bottom panels show the ratio of particle correlations (such as HBT correlations, resonance correlations for peripheral collisions. Nonflow correlations are defined as correlations not related to the reaction plane. The dominant nonflow correlations originating from two-particle correlations (such as HBT correlations, resonance decay) scale as $1/N$ [30], where $N$ is the multiplicity of particles used to determine the event plane. Thus, the nonflow contribution is larger in peripheral collisions. In midcentral and peripheral collisions (10%–20% to 40%–50%), the data of $v_2$[BBC] from 7.7, 11.5, 19.6, and 27 GeV are consistent with $v_2[4]$ and lower than other methods. It suggests that the first-order (BBC) event plane suppresses the second-order nonflow and/or fluctuation effects. Within statistical errors, the results of $v_2$[FTPC] from Au + Au collisions at $\sqrt{s_{NN}} = 39$ GeV are close to $v_2[2]$, $v_2[EP]$, and $v_2$[EtaSubs] in semicentral collisions (10%–20% to 20%–30%). In the peripheral collisions (30%–40% to 60%–70%), $v_2$[FTPC] falls between $v_2$[EtaSubs] and $v_2[4]$. It indicates that the $\eta$ gap between TPC and FTPC reduces the nonflow contribution.

The $p_T$ differential $v_2$ from various methods for the 20%–30% centrality bin are shown in the upper panels of Fig. 5. For comparison, the $v_2$ from other methods are divided by the results of the two-particle cumulant method and shown in the lower panels of Fig. 5. It can be seen that the difference of $v_2[2]$ compared to $v_2[FTPC/BBC]$, $v_2[2]$, and $v_2$[EtaSubs] depends on the $p_T$ range. A larger difference can be observed in the low-$p_T$ region ($p_T < 1$ GeV/$c$). Beyond $p_T = 1$ GeV/$c$ the difference stays constant in the measured $p_T$ range. The difference between $v_2[FTPC/BBC]$ and $v_2[4]$ is relatively small and less dependent on $p_T$. It suggests the nonflow contribution to the event plane and two-particle correlation methods depends on $p_T$. Based on the interpretation in Ref. [1], the difference between $v_2[2]^2$ and $v_2[4]^2$ is approximately equal to nonflow plus two times $v_2$ fluctuations. The fact that the ratio of $v_2[4]$ to $v_2[2]$ is closer to 1 at the lower collision energies indicates that the nonflow and/or $v_2$ fluctuations in the $v_2$ measurement depend on the collision energy. One possible explanation is that the nonflow correlations from jets presumably decrease as the collision energy decreases. The results of $v_2[4]$ from $v_2[4]$ in 7.7, 11.5, 19.6, and 27 GeV, while the $v_2[FTPC]$ is larger than $v_2[4]$ in 39 GeV. This consistency can be also observed in Fig. 4 for 10%–20% to 40%–50% centrality bins. It indicates that the use of the first-order reaction plane (BBC event plane) to study the second harmonic flow eliminates flow fluctuations which are not correlated between different harmonics. The first-order BBC reaction plane is struck by nucleon spectators for these beam energies. The contribution of spectators makes the BBC event plane more sensitive to the reaction plane. This could partly explain the consistency between $v_2$[BBC] and $v_2[4]$ mentioned above. More studies of the collision-energy dependence of nonflow and flow fluctuations will be discussed in another paper.

### C. Systematic uncertainties

Different $v_2$ methods show different sensitivities to nonflow correlations and $v_2$ fluctuations. In previous STAR publications, the differences between different methods were regarded as systematic uncertainties [11,12]. A great deal of progress has revealed that some of these differences are not attributable to systematic uncertainties in different methods, but attributable to different sensitivities to nonflow and flow fluctuation effects [35,52]. The four-particle cumulant method is less sensitive to nonflow correlations [32,33] and has a negative contribution from flow fluctuations. $v_2$ measurements from the two-particle cumulant method and the event-plane method (the second harmonic event plane) have positive contributions from flow fluctuations as well as nonflow. It was also noticed that four-particle cumulant results should be very close to flow in the reaction plane, while the two-particle cumulant measures flow in the participant plane [35,52]. Further, because of the large pseudorapidity gap between the BBC/FTPC and TPC, $v_2$[BBC] and $v_2[FTPC]$ are most insensitive to nonflow correlations.
We estimate the systematic uncertainty on event-plane flattening methods for $v_2$[EP] and $v_2$[EtaSubs] by the difference between them and find it to be negligible (below 1%). A 5% systematic uncertainty on $v_2$(BBC), $v_2$(FTPC), $v_2$(EP), and $v_2$(EtaSubs) is estimated by varying cut parameters (e.g., collision vertex position, the DCA to the primary vertex for the tracks, and the number of fit points used for reconstruction of the tracks). The systematic uncertainties on $v_2$[2] and $v_2$[4] are based on the difference between $Q$-cumulant and GF-cumulant methods (5%) as well as cut variations (5%). All the percentage uncertainties are relative to the $v_2$ value.

V. DISCUSSION

A. Transverse momentum and centrality dependence of $v_2$

The centrality dependence of $p_T$ differential $v_2$ with respect to the initial eccentricity has been studied in detail for Au + Au and Cu + Cu collisions in $\sqrt{s_{NN}} = 200$ and 62.4 GeV [12,13]. The larger magnitude of $v_2$ in the more peripheral collisions could be attributable to the larger initial eccentricity in coordinate space for the more peripheral collisions. The participant eccentricity is the initial configuration space eccentricity of the participant nucleons defined by Eq. (3). The root-mean-square participant eccentricity, $\epsilon_{\text{part}}[2]$, is calculated from the MC Glauber model [53,54] (Table II) and color glass condensate (CGC) model [55–58] (Table III). The event plane is constructed from hadrons which have their origin in participant nucleons. At the same time, the event-plane resolution ($\eta$ subevent) is less than 0.5. Thus, what we actually measure is the root-mean-square of $v_2$ with respect to the participant plane [52]. In this case, $\epsilon_{\text{part}}[2]$ is the appropriate measure of the initial geometric anisotropy taking the event-by-event fluctuations into account [52,59,60]. In Figs. 6 and 7, the centrality dependence of

![Figure 6](image_url)

</tbody>
</table>
p_{T}\) differential \(v_2\) over eccentricity is shown for Au + Au collisions at √sNN = 7.7, 11.5, 19.6, 27, and 39 GeV. For all five collision energies, the centrality dependence of \(v_2(p_{T})\) is observed to be similar to that at higher collision energies (62.4 and 200 GeV) of Au + Au and Cu + Cu colliding systems. That central collisions in general have higher \(v_2/\varepsilon\) than peripheral collisions is consistent with the picture that collective interactions are stronger in collisions with larger numbers of participants.

### B. Pseudorapidity dependence

The panel (a) of Fig. 8 shows \(v_2\) as a function of pseudorapidity for Au + Au collisions at √sNN = 7.7, 11.5, 19.6, 27, 39, 62.4, and 200 GeV in midcentral (10%–40%) collisions. The data for √sNN = 62.4 and 200 GeV are from Refs. [12,61,62]. To facilitate comparison with 62.4 and 200 GeV data, the results of \(v_2(\text{EP})\) are selected for the rest of the collision energies. The 7.7-GeV data are empirically fit by the following function:

\[
v_2(\eta) = p_0 + p_1 \eta^2 + p_2 \eta^4, \tag{45}
\]

with parameters \(p_0 = 0.0450 \pm 0.0002\), \(p_1 = -0.0064 \pm 0.0015\), \(p_2 = -0.0024 \pm 0.0017\). For clarity, panel (c) of Fig. 8 shows the ratio of \(v_2(\eta)\) with respect to each fit function. The pseudorapidity dependence of \(v_2\) indicates a change in shape as we move from √sNN = 200 GeV to 7.7 GeV within our measured range \(-1 < \eta < 1\).

To investigate the collision energy dependence of the \(v_2(\eta)\) shape, in panels (b) and (d) of Fig. 8, the same \(v_2\) results have been plotted as a function of pseudorapidity divided by beam rapidity. The data of 7.7 GeV are fit by Eq. (45) with parameters \(p_0 = 0.0450 \pm 0.0002\), \(p_1 = -0.0279 \pm 0.0064\), and \(p_2 = -0.0464 \pm 0.0325\). The beam rapidities are 2.09, 2.50, 3.04, 3.36, 3.73, 4.20, and 5.36 for √sNN = 7.7, 11.5, 19.6, 27, 39, 62.4, and 200 GeV, respectively. After dividing pseudorapidity by the beam rapidity, the shape of \(v_2\) seems similar at all collision energies. The approximate beam rapidity scaling on the \(v_2(\eta)\) shape suggests the change in shape may be related to the final particle density. Higher particle density indicates higher probability of interaction, which can generate larger collective flow.

### FIG. 7. (Color online) The \(v_2\) over \(\varepsilon\) (CGC) as a function of \(p_{T}\) for various collision centralities (10%–20%, 30%–40%, and 50%–60%) in Au + Au collisions at midrapidity. Panels (a), (b), (c), (d), and (e) show the results for √sNN = 7.7, 11.5, 19.6, 27, and 39 GeV, respectively. The data are from v2[EtaSubs]. The error bars and shaded boxes represent the statistical and systematic uncertainties respectively, as described in Sec. IV C.

### FIG. 8. (Color online) Panel (a) shows the \(v_2(\text{EP})\) vs \(\eta\) for 10%–40% centrality in Au + Au collisions at √sNN = 7.7, 11.5, 19.6, 27, 39, 62.4, and 200 GeV. Panel (c) shows the ratio of \(v_2\) vs \(\eta\) for all √sNN with respect to the fit curve. Panel (b) shows the \(v_2(\text{EP})\) vs \(\eta/\varepsilon\) beam. Panel (d) shows the ratio of \(v_2\) vs \(\eta/\varepsilon\) beam for all √sNN with respect to the fit curve. The data for √sNN = 62.4 and 200 GeV are from Refs. [12,61,62]. The dashed red curves show the empirical fit to the results from Au + Au collisions at √sNN = 7.7 GeV. The bands show the systematic uncertainties as described in Sec. IV C.

### FIG. 9. (Color online) The top panels show \(v_2[4]\) vs \(p_{T}\) at midrapidity for various collision energies (√sNN = 7.7 GeV to 2.76 TeV). The results for √sNN = 7.7 to 200 GeV are for Au + Au collisions and those for 2.76 TeV are for Pb + Pb collisions. The dashed red curves show the empirical fits to the results from Au + Au collisions at √sNN = 200 GeV. The bottom panels show the ratio of \(v_2[4]\) vs \(p_{T}\) for all √sNN with respect to the fit curve. The results are shown for three collision centrality classes: 10%–20% (a1), 20%–30% (b1), and 30%–40% (c1). Error bars are shown only for the statistical uncertainties.
C. Energy dependence

One of the most important experimental observations at RHIC is the significant $v_2$ signal in the top energy of Au + Au collisions [6,10] (more than 50% larger than at the SPS [63]). It could be interpreted as the observation of a higher degree of thermalization than at lower collision energies [6]. The BES data from the RHIC-STAR experiment offers an opportunity to study the collision energy dependence of $v_2$ using a wide acceptance detector at midrapidity. Figure 9 shows the $p_T$ dependence of $v_2[4]$ from $\sqrt{s_{NN}} = 7.7$ GeV to 2.76 TeV in 10%–20% (a1), 20%–30% (b1), and 30%–40% (c1) centrality bins, where the ALICE results in Pb + Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV are taken from Ref. [18]. The reasons to select the results of $v_2[4]$ for the comparison are the following: (1) to keep the method for $v_2$ measurements consistent with the published results of ALICE; (2) because $v_2[4]$ is insensitive to nonflow correlations. The 200-GeV data are empirically fit by a fifth-order polynomial function. The parameters for the fit function are listed in Table IV. For comparison, the $v_2$ from other energies are divided by the fit results show the difference of $v_2$ for baryon and meson, for example, proton $v_2 <$ pion $v_2$ for $p_T$ below 2 GeV/c, could partly explain the collision energy dependence. Further, in Fig. 10 we compare the experimental data from Fig. 9 (b2) to the viscous hydrodynamic calculations [5]. As the collision energy varies from $\sqrt{s_{NN}} = 7.7$ to 2760 GeV, the experimental data show larger splitting in the lower $p_T$ region and converge at the intermediate range ($p_T \sim 2$ GeV/c), while, in the pure viscous hydrodynamic simulations, the splitting increases with $p_T$. The $p_T$ dependence of the $v_2$ ratio cannot be reproduced by pure viscous hydrodynamic simulations with a constant shear viscosity to entropy density ratio ($\eta/s$) and zero net baryon density. The comparison suggests that a quantitative study at lower collision energies requires a more serious theoretical approach, such as three-dimensional viscous hydro + UrQMD with a consistent EOS at nonzero baryon chemical potential.

Figure 11 shows the energy dependence of $v_2[EtaSubs]$. Larger $v_2[EtaSubs]$ values are observed at higher collision energy for a selected $p_T$ bin, but the $p_T$ dependence of the difference is quite different from $v_2[4]$. The ratios to 39-GeV data for each collision energy first decrease as a function of $p_T$, then slightly increase in the $p_T$ region of 1–2.5 GeV/c. The different trend of the energy dependence of $v_2$ from $v_2[4]$ and $v_2[EtaSubs]$ is interpreted as owing to the different sensitivity of the $v_2$ methods to nonflow and/or flow fluctuations.

![FIG. 10. (Color online) The experimental data (symbols) are the same as in Fig. 9 (b2). The lines represent the viscous hydrodynamic calculations from Ref. [5] based on (a) MC-Glauber initial conditions and $n/s = 0.08$ and (b) MC-KLN initial conditions and $n/s = 0.20."

![FIG. 11. (Color online) The top panels show $v_2[EtaSubs]$ vs $p_T$ at midrapidity for various collision energies ($\sqrt{s_{NN}} = 7.7$ GeV to 39 GeV). The bottom panels show the ratio of $v_2[EtaSubs]$ vs $p_T$ for all $\sqrt{s_{NN}}$ with respect to the 39-GeV data. The results are shown for three collision centrality classes: 10%–20% (a1), 20%–30% (b1), and 30%–40% (c1). Error bars are shown only for the statistical uncertainties."

TABLE IV. Summary of the parameters for the fit functions to the results of $v_2[4]$ vs $p_T$ in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV.

hadron cascade starts. The larger the parton cross section, the AMPT string-melting version incorporates both partonic and hadronic interactions. The larger parton cross section means stronger partonic interactions only take the hadronic interactions into consideration, while the AMPT default and UrQMD models parameter settings for the models follow the recommendation of the cited references. The AMPT default and UrQMD models incorporate both partonic and hadronic potentials affect the final results of the models.

**D. Model comparisons**

To investigate the partonic and hadronic contribution to the final $v_2$ results from different collision energies, transport model calculations from AMPT default (version 1.11), AMPT string melting (version 2.11) [64], and UrQMD (version 2.3) [65] are compared with the new data presented. The initial parameter settings for the models follow the recommendation in the cited references. The AMPT default and UrQMD models only take the hadronic interactions into consideration, while the AMPT string-melting version incorporates both partonic and hadronic interactions. The larger the parton cross section, the larger the hadron cascade starts.

Figure 12 shows the comparison of $p_T$ differential $v_2(4)$ between model and data in the 20%–30% centrality bin. The 200-GeV data are taken from Ref. [62]. The figure shows that UrQMD underpredicts the measurements at $\sqrt{s_{NN}} = 39$ and 200 GeV in the $p_T$ range studied. The differences are reduced as the collision energy decreases. That the ratio of data to UrQMD results are closer to 1 at the lower collision energy indicates that the contribution of hadronic interactions becomes more significant at lower collision energies. The AMPT model with default settings underpredicts the 200-GeV data, while the ratios of data to AMPT default results show no significant change from 7.7 to 39 GeV. The inconsistency between AMPT default and UrQMD makes the conclusion model dependent. The AMPT model with string-melting version with 3- and 10-mb parton cross sections overpredicts the results at all collision energies from 7.7 to 200 GeV. A larger parton cross section means stronger partonic interactions which translate into a larger magnitude of $v_2$. The difference between data and these AMPT model calculations seems to show no significantly systematic change vs collision energies. However, a recent study with the AMPT model suggests hadronic potentials affect the final $v_2$ results significantly when the collision energy is less than $\sqrt{s_{NN}} = 39$ GeV [66].

**VI. SUMMARY**

We have presented elliptic flow, $v_2$, measurements from Au + Au collisions at $\sqrt{s_{NN}} = 7.7, 11.5, 19.6, 27$, and 39 GeV for inclusive charged hadrons at midrapidity. To investigate nonflow correlations and $v_2$ fluctuations, various measurement methods have been used in the analysis. The difference between $v_2[2]$ and $v_2[4]$ decreases with decrease in collision energy, indicating that nonflow contribution and/or flow fluctuations decrease with a decrease in collision energy. The centrality and $p_T$ dependence of $v_2$ are similar to that observed at higher RHIC collision energies. A larger $v_2$ is observed in more peripheral collisions. The pseudorapidity dependence of $v_2$ indicates a change in shape from 200 to 7.7 GeV within the measured range $-1 < \eta < 1$, but the results of $v_2$ versus pseudorapidity scaled by beam rapidity shows a similar trend for all collision energies. The comparison with Au + Au collisions at higher energies at RHIC ($\sqrt{s_{NN}} = 62.4$ and 200 GeV) and at LHC (Pb + Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV) shows the $v_2[4]$ values at low $p_T$ ($p_T < 2.0$ GeV/c) increase with increase in collision energy implying an increase of collectivity. The current viscous hydrodynamic simulations cannot reproduce the trend of the energy dependence of $v_2(p_T)$.

The agreement between the data and UrQMD, which is based on hadronic rescatterings, improves at lower collision energies, consistent with an increasing role of the hadronic stage at these energies. The inconsistency between AMPT default and UrQMD makes the conclusion model dependent. The comparison to AMPT model calculations seems to show no significantly systematic change vs collision energy, but im-

FIG. 12. (Color online) The $v_2(4)$ as a function of $p_T$ for 20%–30% Au + Au collisions at $\sqrt{s_{NN}} = 7.7, 11.5, 39$, and 200 GeV compared to corresponding results from UrQMD, AMPT default version, and AMPT with string melting version (3 and 10 mb). The shaded boxes show the systematic uncertainties for the experimental data of 7.7, 11.5, and 39 GeV. The bottom panels show the ratio of data to the fit results of the models.
proved calculations including harmonic potentials may change the $v_2$ values from AMPT models at lower collision energies. These results set the baseline to study the number of constituent quark scaling of identified hadron $v_2$. It also sets the stage for understanding the collision energy dependence of $v_2$ in the regime where the relative contribution of baryon and mesons vary significantly.
