Keywords: Last Glacial Maximum, regional ocean sea-ice model, Arctic Ocean, CLIMAP, GLAMAP, NAOSIM, sea-ice drift

1 Abstract

2 Due to the lack of data, the extent, thickness and drift patterns of sea ice and icebergs in the glacial
3 Arctic remains poorly constrained. Earlier studies are contradictory proposing either a cessation of
4 the marine cryosphere or an ice drift system operating like present-day. Here we examine the
5 marine Arctic cryosphere during the Last Glacial Maximum (LGM) using a high-resolution,
6 regional ocean-sea ice model. Whereas modern sea ice in the western Arctic Basin can circulate in
7 the Beaufort Gyre for decades, our model studies present an extreme shortcut of glacial ice drift. In
8 more detail, our results show a clockwise sea-ice drift in the western Arctic Basin that merges into a
9 direct trans-Arctic path towards Fram Strait. This is consistent with dated ice plough marks on the
10 seafloor, which show the orientation of iceberg drift in this direction. Also ice-transported iron-
11 oxide grains deposited in Fram Strait, can be matched by their chemical composition to similar
12 grains found in potential sources from the entire circum-Arctic. The model results indicate that the
13 pattern of Arctic sea-ice drift during the LGM is established by wind fields and seems to be a
14 general feature of the glacial ocean. Our model results do not indicate a cessation in ice drift during
15 the LGM.

16 1. Introduction

17 The nature of the Arctic sea ice cover during late Pleistocene glaciations is still debated, ranging
18 from a perennial sea-ice cover to that of a near kilometre thick ice shelf covering the entire basin
19 that would essentially halt ice drift (e.g., Jakobsson et al., 2010 and publications referenced therein;
20 Grosswald and Hughes, 2008). Recently published stratigraphic data at the Northwind Ridge close
21 to Chukchi margin (Polyak et al., 2007) show some evidence for ice-grounding shallower than
22 1,000 m water depth during the Last Glacial Maximum (LGM) 23–19 thousand years before present
23 (ka BP). Most of geophysical/geological evidence is thought to have formed in Marine Isotope
24 Stage (MIS) 6 (~185–132 ka BP) and was retrieved from various sites, including ice streamlines at
25 Yermak Plateau near Fram Strait, Morris Jessup Rise north of Greenland, at the Lomonosov-Ridge
26 close to the North Pole, Mendeleev Ridge, Northwind Ridge and Chukchi Plateau and Alaska
27 Beaufort Margin, which do not support the idea of a shelf ice cover of Antarctic type during the
28 LGM (Jakobsson et al., 2010). However, there are still extremes of postulated glacial sea-ice drift,
29 varying from no substantial change from today (Phillips and Grantz, 2001) to a resting ice massif
30 with only occasional break-up north of Fram Strait (Nørgaard-Pedersen et al., 2003; Bradley and
31 England, 2008).

32 In the central Arctic Ocean, LGM climate reconstructions are limited and challenging due to low
33 sedimentation rates and bioproduction (Nørgaard-Pedersen et al., 1998; Stein, 2008; Stein et al.,
34 1994). Polyak et al. (2004) present a sedimentary record of the Mendeleev Ridge confirming that
35 LGM sediments poorly conserve biological remains (benthic and planktonic foraminifers) favouring
36 the interpretation of a thick lid of pack ice or even an ice-shelf covering the western Arctic Ocean.
37 Along the continental margin at Fram Strait where modern North Atlantic waters are penetrating the
38 Arctic Ocean. Nørgaard-Pedersen et al. (2003) suggest seasonal open water conditions and north of
39 Fram Strait a glacial perennial ice cover. Bradley and England (2008) conclude that seasonal open
40 water conditions along the coast from the northern edge of the Barents Sea ice-sheet to the Laptev
41 Sea shelf edge existed caused by narrow coastal boundary currents or offshore katabatic winds

(Knies et al., 1999; Vogt et al., 2001). Contrary to these findings, Müller et al. (2009) propose a permanent LGM sea-ice cover based on Biomarker data at the northern Fram Strait location (Core PS2837-5; Lat 81°13'N, Long 02°22'E).

A milestone in illuminating the LGM and providing data for numerical modeling was the first comprehensive reconstruction of global surface conditions provided by the CLIMAP (Climate: Long range Investigation, Mapping, And Prediction, 1981) project, including seasonal sea surface temperatures (SST) and extent of sea ice. CLIMAP (1981) proposed perennial ice cover in the central Arctic Ocean and Nordic Seas implying a shutdown of the northern North Atlantic inflow and seasonal sea-ice cover in the North Atlantic down to 50°N latitude. These findings have been revised and expanded by SST reconstructions in the Atlantic sector of the GLAMAP Group (Pflaumann et al., 2003) that show a discrepancy of 8°C warmer summer temperatures in the Nordic Seas. Along the Faroe-Shetland Passage, Hebbeln et al. (1994) also observed limited sea-ice expansion with seasonally open, warmer waters in the Greenland and Norwegian Seas. However, quantitative reconstructions of SST in Nordic Seas based on different proxies diverge by more than 10°C (de Vernal et al., 2006). They relate potential discrepancies among the proxies to diverse salinity tolerance, trophic levels, taphonomy and lateral advection. For example, Mg/Ca ratios indicate surface temperatures up to 10°C (Meland et al., 2005), whereas $\delta^{18}\text{O}$ values suggest less than 4°C both derived from shells of *N. pachyderma* assemblages at Nordic Seas (de Vernal et al., 2006). In light of the proxy uncertainties and different hypotheses of late Pleistocene glaciations in the Arctic, we address the glacial sea ice and ocean circulation by a numerical model instead. For this purpose, we deploy a regional ocean-sea ice model that has been used in recent studies (e.g., Kauker et al., 2003) and operational sea-ice cover predictions (Kauker et al., 2009), and we equip it with boundary conditions that are representative of the LGM. We use this regional ocean-sea ice model to investigate the glacial Arctic sea ice system and propose a model- and proxy-based ice drift reconstruction for the LGM.

67

68

69 2. Methods and data

70 2.1 Experimental design

71 The model studies use the North Atlantic/Arctic Ocean Sea Ice Model (NAOSIM), developed at the
72 Alfred Wegener Institute (Kauker et al., 2003; Köberle and Gerdes, 2003). The spatial domain of
73 the ocean/sea-ice model captures the Arctic Ocean, the Nordic Seas and the northern North Atlantic
74 (90°N – 50°N). The model has a horizontal resolution of $0.25^{\circ} \times 0.25^{\circ}$ per grid box ($\sim 27 \times 27$ km,
75 respectively) and 30 unevenly spaced levels in the vertical. A dynamic-thermodynamic sea ice
76 model with a viscous plastic rheology (Hibler, 1979) is coupled to the ocean model (Kauker et al.,
77 2003).

78

79 2.1.1 Atmospheric forcing

80 The present model studies are forced by differing atmospheric boundary conditions including the
81 parameters 2 m air temperature above surface, dew point temperature, cloudiness, precipitation,
82 zonal and meridional component of wind speed, and surface wind stress. The modern control run
83 (CTRL) is forced by atmospheric data fields provided by the NCEP/NCAR reanalysis project
84 (Kalnay et al., 1996), whereas glacial atmospheric data was generated by simulations of an
85 atmospheric general circulation model (Lohmann and Lorenz, 2000; Romanova et al., 2004). The
86 atmospheric boundary forcing of model study LGMC is derived from a dataset of the global
87 atmospheric model ECHAM3/T42L19, which was adapted to the glacial boundary conditions by
88 Lohmann and Lorenz (2000). In one sensitivity study that used sea surface temperature, ice cover as
89 well as albedo reconstruction as per CLIMAP (1981), Lohmann and Lorenz (2000) decreased
90 CLIMAP SSTs in the tropics (30°S – 30°N) by 3°C . Compared to the standard atmospheric LGM
91 run, the sensitivity study with artificial cooling in the tropics is in better agreement with marine and
92 terrestrial proxy data (Lohmann and Lorenz, 2000) and is used as present atmospheric boundary
93 forcing for LGMC.

94 For another model study (LGMG), the atmospheric data fields are provided by the same atmosphere
95 model, ECHAM3/T42L19 with glacial setup (Romanova et al., 2004). LGMG atmospheric
96 boundary conditions are forced by glacial SST, albedo, and sea ice reconstruction of the Atlantic
97 region provided by GLAMAP 2000 (Glacial Atlantic Ocean Mapping; Paul and Schäfer-Neth,
98 2003). In contrast to CLIMAP (1981), reconstructions of GLAMAP 2000 exhibit year-round
99 warmer SSTs in North Atlantic and summer ice free conditions in the central and eastern part of the
100 Nordic Seas with winter expansion south of Iceland and Faeroe (Pflaumann et al., 2003). The
101 atmospheric data fields force NAOSIM twice per day and are repeated over a 15 year cycle.

102

103 2.1.2 Glacial Arctic freshwater budget

104 So far, knowledge of the glacial Arctic freshwater budget is sparse. In general the glacial circum
105 Arctic ice sheets hindered the northward transport of latent heat (see Stein, 2008). This resulted in
106 an isolated Arctic domain characterized by decreased temperatures and humidity and in
107 consequence with reduced meteoric precipitation and a weakened hydrological cycle (Lohmann and
108 Lorenz, 2000). The Pacific westerlies are split into a shifted branch southward to the flank of the
109 Laurentide ice sheet at 40-50°N latitude (Clark et al., 1999; Lambeck et al., 2002) and a northward
110 excursion across the Canadian Arctic as indicated by modeling results (e.g. Lohmann and Lorenz,
111 2000). The Siberian sector is influenced by cold, dry winds on the lee side of the Fenno-
112 Scandinavian ice sheet (Hubberten et al., 2004; Siegert and Marsiat, 2001; Siegert and Dowdeswell,
113 2004) as well as an anticyclonic regime over Siberia that hinders the advection of Atlantic air
114 masses (Arkipov et al., 1986; Velichko et al., 1997). Furthermore, the Bering Land Bridge
115 connecting Asia and North America is blocking the Pacific inflow of freshwater for the Arctic
116 Ocean. As a consequence the total freshwater budget for the Arctic Ocean is decreased (Martinson
117 and Pitman, 2007). The presumed glacial Arctic river inflow roughly corresponds to half (1,800
118 km³/a) of today's annual budget of 3,300 km³/a (Aagaard and Carmack, 1989), which ranges

119 between glacial runoff in the AGCM ($1,082 \text{ km}^3/\text{a}$) and a modeling study using a more realistic
120 river routing ($\sim 2,000 \text{ km}^3/\text{a}$; Alkama et al., 2008).

121 The model takes into account changes in salinity by water transport, precipitation, snowmelt, sea ice
122 melting, freezing, and river runoff. Apart from the salinity advection term in the ocean, salinity
123 fluxes in the model are not associated with momentum and volume. An additional salinity restoring
124 term at the sea surface using the present climatology of salinity fields (Levitus and Boyer, 1994;
125 Levitus et al., 1994; National Snow and Ice Data Center, 1997), prevents the model climate from
126 broadly drifting in the Arctic Ocean and is necessary to obtain a halocline (Steele et al., 2001). The
127 restoring term has a long time scale of 180 days and the additional freshwater flux adds $\sim 17 \text{ mm/a}$
128 to the Arctic Ocean. The salinity restoring term is applied to all model studies presented here. In
129 one sensitivity study (LGMC_sal), we applied glacial sea surface salinity from a climate model
130 output (Shin et al., 2003a, b) in order to discuss the impact on the results.

131 2.1.3 Model setup

132 The control run (CTRL) uses the ocean/sea-ice model used by Kauker et al. (2003) and Köberle and
133 Gerdes (2003). The atmospheric forcing data consists of the NCEP/NCAR reanalysis project
134 (Kalnay et al., 1996) for the period 1948–2007. The last 30 years (1977–2007) of CTRL are used
135 for comparison with the glacial sensitivity studies. For the change in morphology of the glacial
136 ocean, the present-day land-sea mask (NOAA, 1988) is adapted to the ice sheets in the Northern
137 Hemisphere (Ehlers and Gibbard, 2007) and sea level is lowered by 120 m (Fairbanks, 1989).
138 Thermodynamic processes on a sub-grid scale, like open water areas between sea-ice, seven ice
139 classes are defined following a Gaussian distribution around the mean sea-ice thickness. Model
140 studies without limitations show sea-ice thickness $> 80 \text{ m}$ after 120 modeled years along the
141 northern Barents Sea shelf edge, north of Greenland and Baffin Bay without reaching an
142 equilibrated sea-ice thickness. In the glacial model runs, the potential mean sea-ice thickness of
143 each grid cell is limited to a maximum of 30 m in order to reach equilibrium. The upper limit of
144 mean sea-ice thickness in the sea-ice model was motivated by the maximum height of pressure

145 ridges observed by present-day observations of first-year ice as reported by Polyak et al. (2010). As
 146 a consequence of the glacial water storage over land, an additional increase in salinity of 1 psu
 147 (practical salinity unit) is prescribed for the open boundary condition of the northern North Atlantic
 148 inflow. In order to account for a temperature decrease, the lateral temperature at the southern
 149 boundary is reduced by 2°C, consistent with global ocean simulations (e.g., Butzin et al., 2005).
 150 Experiments testing the prescribed southern boundary characteristics (barotropic stream function)
 151 with a glacial model setup have only minor effects on the through flow of the Arctic Ocean (cf. Fig.
 152 S8).
 153 The ocean model is initialized by an LGM simulation of a general circulation model (NCAR-
 154 CCSM; Shin et al., 2003a, b) and the initial conditions of the sea-ice model (zonal and meridional
 155 component of sea-ice drift velocities, snow-cover thickness, sea-ice thickness) are set to zero to
 156 avoid any preconditioning.
 157 We note that the total water mass of the upper Arctic Ocean layer (0–1,000 m) of the NAOSIM
 158 present-day setup is typically exchanged within 30 years (Karcher and Oberhuber, 2002) in
 159 agreement with observations on tracer contaminants (MacDonald and Bewers 1996; MacDonald et
 160 al. 2004). The lengths of the model runs are 120 model years, only the last 30 years are used for
 161 analysis. Major contribution of present water mass exchange happens through western Fram Strait,
 162 where salty and warm Atlantic waters enter the Arctic Ocean in the upper ~200 m (Fig. S7a). All of
 163 our glacial model simulations exhibit a displaced inflow of bottom waters >2m/s stronger than the
 164 Atlantic Water Current in CTRL, which equals an increase of surface outflow of the Arctic Ocean
 165 because of mass conservation (Fig. S7b–f, Fig. S8). Changes in the barotropic stream function
 166 ($\pm 50\%$ psi compared to LGMC) at the southern boundary of the prescribed northern North Atlantic
 167 inflow as already shown for present-day conditions (Kauker et al., 2005) don't significantly impact
 168 rates of water exchange at Fram Strait (Fig. S8). In response experiments with present-day setup
 169 Kauker et al. (2005) state that barotropic anomalies at 50°N latitude do not pass the Greenland-
 170 Scotland Ridge, but an increase of 2°C for the upper 500 m of the southern boundary water column

171 effectively warms the West Spitsbergen Current by $\sim 0.5^{\circ}\text{C}$ (as shown in 300 m depth) within two
172 years.

173 In order to analyze the importance of glacial wind fields with respect to the respective SST
174 reconstruction and the presence of glacial ice sheets, we performed another sensitivity study. The
175 sensitivity study (LGMC_PDw, LGMG_PDw) uses the glacial setup (LGMC, LGMG) and is run
176 with present-day wind fields (Lohmann and Lorenz, 2000).

177 2.2 Geological data

178 The sedimentary record shown in Fig. 1 is derived from AMS¹⁴C-dated box core PS1230 (Lat
179 $78^{\circ}51'\text{N}$, Long $04^{\circ}46'\text{W}$; 1,235 m below sea level; Darby et al., 2002; Darby and Zimmerman,
180 2008), which is located at the centre of modern sea-ice export through Fram Strait (Vinje et al.,
181 1998). Using a geochemical fingerprinting method, Darby et al. (2002) and Darby and Zimmerman
182 (2008) are able to identify the source of individual detrital iron oxide minerals (in the 45-250 μm
183 fraction) transported by sea ice and/or icebergs. Geographically distinct sources of sea-ice
184 formation and/or iceberg calving are identified by >2000 circum-Arctic compositional groups
185 applying statistical analysis (clustering and discriminant function analysis; Darby et al., 2002). The
186 statistical approach typically matches 50-60% of the analyzed grains per sample (~ 100 grains),
187 therefore a weighted percentage (wt%) is used to avoid anomalously large percentages when grain
188 numbers are low (Zimmerman and Darby, 2008). In general, the sedimentary record shows an
189 elevated level of coarse IRD during late MIS3 ($\sim 60\text{--}27$ ka BP) and MIS2 ($\sim 27\text{--}12$ ka BP) including
190 the LGM (Fig.1, marked in blue), whereas the Holocene signal (12–0ka) is dominated by fine-
191 grained sediment ($<10\%$ coarse fraction; marked in red). The fine-grained nature of this Holocene
192 sediment suggests sea-ice rafted debris (Pfirman et al., 1989; Reimnitz et al., 1998; Nürnberg et al.,
193 1994; Darby et al., 2011). For the reconstruction of glacial/interglacial ice-drift pattern (Fig. 1, solid
194 blue and dashed red lines) the same method was applied to a transect of sediment cores bisecting
195 the central Arctic Ocean (Bischof and Darby, 1997).

196 Furthermore geophysical evidence of the sea-floor along the Alaska-Beaufort margin (Engels et al.,
197 2008) and Chukchi-Borderland (Polyak et al., 2001; 2007) show glaciogenic iceberg scours, which
198 indicate grounding of large ice masses and the direction of ice drift that are used for model
199 comparison (Fig. 1).

200

201 3. Results

202 3.1 Simulation of Arctic sea-ice dynamics and thermodynamics

203 For CTRL, mean westerlies are >4.5 m/s in the northern North Atlantic sector and katabatic winds
204 are localized above the Greenland ice sheet (Fig. 2). The Nordic Seas of LGMC are enclosed by
205 katabatic winds off the eastern flank of Greenland ice sheet and the western flank of the Barents Sea
206 ice sheet, whereas the speed of westerlies is reduced compared to CTRL. The wind speeds in
207 LGMG compared to LGMC are larger in general and form an anomalous Icelandic Low (Fig. 2c).
208 In the central Arctic Ocean, a closed perennial sea-ice cover with mean thickness of 3 m is found
209 (Fig. 4a). Perennial ice, >8 m thick, is observed primarily in parts of the northern coast of the
210 Canadian Archipelago and the coast of northern Greenland (Fig. 4a). The sea-ice drift follows the
211 Beaufort Gyre and Transpolar Drift (Fig. 5a) exiting the Arctic Ocean through Fram Strait. Today's
212 single year sea-ice, represented by present day control run (CTRL), evolves and melts in the circum
213 Arctic shelf-seas and further south especially in Baffin Bay and along the East Greenland Current
214 within a year (Fig. 3a,d). The minimum of modern sea-ice export across Fram Strait is directly
215 linked to the minimum sea-ice extent in late summer (Fig. 3, Fig. 6) with a dramatic drop of sea-ice
216 velocities starting in May (9.4 cm/s) and reaching its minimum in September (2.3 cm/s) before
217 recovering (Fig. S5). Present locations of sea-ice formation include the entire circum-Arctic
218 shelves, especially the expansive, shallow marine shelf areas of the Laptev, Kara and East Siberian
219 Seas (not shown).

220 In contrast, the central glacial Arctic Ocean in LGMG and LGMC is almost completely isolated
221 from the atmosphere by a perennial sea-ice cover throughout the year (Fig. 3). Only in the Beaufort

222 Sea, along the shelf edge of the Canadian Archipelago is sea ice produced within open water areas
223 (polynyas) (Fig. 3). The northern branch of Pacific westerlies, which are split by the Laurentide ice-
224 sheet is directed towards the Beaufort Sea and Canadian Archipelago (Fig. 2). There, early stage sea
225 ice is pushed offshore into the Beaufort Sea and open water surfaces are conserved along the coast
226 (Fig. 3; Fig. 4). At the northern Barents, Kara, and Laptev Sea shelf edge enclosing the Eurasian
227 Basin, sea ice is stuck (<0.2 cm/s sea-ice drift) along the rim and reaches the upper limit of
228 prescribed ice thickness (Fig. 4 b. c). Further north of the rim and along the Siberian shelf edge
229 August sea-ice cover declines to $<50\%$ in LGMG and $<60\%$ in LGMC (Fig. 3 b, c). This is mainly
230 caused by ice dynamics, since surface air temperatures during summer rarely reach positive values
231 and surface ocean waters are close to the freezing point (not shown).

232 A general zonal gradient of sea-ice thickness in the Nordic Seas (Fig. 4) is maintained by two flow
233 patterns: The northward inflow of warm, salty North Atlantic waters along the Norwegian and West
234 Spitsbergen Current in addition to katabatic winds offshore of the Barents Sea ice sheet (Fig. 2)
235 limit sea-ice cover there (Fig. 4). The southward East Greenland Current (EGC) carries cold,
236 relatively fresh water and sea ice from the Arctic. Along the EGC, a permanent sea-ice cover arises
237 and extends to the oceanic polar front, which separates polar and Arctic water masses (Fig. 3). In
238 contrast, seasonal sea-ice production occurs in the Arctic and Atlantic waters of the Nordic Seas. In
239 LGMG less sea-ice concentration than LGMC with seasonally open water conditions along a more
240 pronounced North Atlantic inflow is shown in the Nordic Seas (Fig. 3b, e; Fig. 4b). Baffin Bay is
241 characterized by a permanent, static sea-ice cover and sea-ice thickness close to the artificial limit
242 of 30 m (Fig. 3; Fig. 4b, c). In the southern region of Baffin Bay, the sea-ice cover destabilizes (Fig.
243 4b, c), and inter-annual ice-free areas emerge at the West Greenland coast of the Labrador Sea,
244 where sea ice is formed again. The juvenile sea ice in the Beaufort Sea moves anti-cyclonally across
245 the Canadian Basin and merges with a transpolar drift towards Fram Strait (Fig. 5b, c). In the glacial
246 scenarios, the gyre of sea-ice drift is centered in the Amerasian Basin further towards the Ellesmere
247 Island compared to CTRL. Generally the colder glacial climate scenario based on CLIMAP data

248 shows a slow linear stream flow pattern directly towards Fram Strait. North of Ellesmere Island
249 glacial sea ice either gets entrapped in the anticyclonic gyre (LGMG) or takes a direct pathway
250 along the coast of Greenland to Fram Strait (LGMC). In contrast to present-day sea-ice export, the
251 Laptev-Sea and Kara-Sea shelf edge barely show offshore transport of ice. Along the Barents and
252 Kara Sea shelf edge, sea-ice drift is comparably faster in LGMG than in LGMC (Fig. 5b, c).

254 3.2 Water mass characteristics at Fram Strait and in the central Arctic Ocean

255 The sea-ice drift in the glacial Arctic Basin is a result of a balance between wind stress and ocean
256 drag (and internal ice stress). In order to understand the contribution of ocean drag, it is necessary to
257 analyse the vertical structure of water masses. For present day (CTRL) the mean sea surface salinity
258 fields of the central Arctic domain are ~31psu and ~33psu for LGMG and LGMC, respectively (see
259 supplementary Fig. S1a, b, c). The halocline in the central Arctic Ocean is situated at ~200 m for
260 CTRL and ~80 m for the glacial sensitivity studies and a barotropic mode prevails (LGMG, LGMC,
261 Fig. S1d, e, f). All presented glacial simulations show enhanced Arctic inflow of Atlantic bottom
262 waters (ca. -3.5 m/s), colder ($<-1.8^{\circ}\text{C}$) and saltier ($>36\text{psu}$) than present day, and the outflow of
263 fresh Arctic waters at the water surface. At the present location of the West Spitsbergen Current
264 glacial model studies exhibit a similar to present day maximum speed ($\sim 1\text{ m/s}$) of waters entering
265 the Arctic. Along the East Greenland Current the outflow is centered at around 200 m water depth
266 through Fram Strait. Since the present-day Atlantic water inflow is shifted towards the bottom, an
267 Arctic boundary current west of Svalbard exhale through Fram Strait (Fig. S7b–f, Fig. S8). The
268 boundary current is consistent with the general ocean circulation in the central Arctic Ocean of the
269 glacial model scenarios (not shown). For the glacial model studies the water passage through the
270 Barents Sea is blocked by an ice sheet which potentially redirects a branch of the North Atlantic
271 Current towards Fram Strait leading to increased water mass exchange at this location. Modulations
272 of the Atlantic water stream function at the southern boundary of the model do not affect water
273 properties at Fram Strait (Fig. S8). A similar effect has been reported by Kauker et al. (2005) for

274 present-day conditions. We note that deeper levels of the ocean model are not in full equilibrium
275 (see supplement). Based on LGM1 we set up a sensitivity study for the surface salinity restoring
276 term using surface salinity fields derived from the NCAR-CCSM output (Shin et al., 2003a, b). For
277 the glacial Arctic Ocean the surface salinity anomaly of the new restoring term is higher than
278 LGM1, but the overall large-scale effect is almost additive (Fig. S2a). The absence of relative fresh
279 Pacific waters in the Beaufort Sea is mimicked by the surface salinity restoring term with maximum
280 surface salinity anomalies of ~4psu (Fig. S2a). An increase of salinity in the Arctic surface waters
281 (Fig. S2a) deepens the halocline as indicated at the Fram Strait section (Fig. S7d). The exchange of
282 water masses at Fram Strait is decreased and similar in pattern compared to other glacial model
283 studies, but still higher than present-day. Higher surface salinity can also impact the formation of
284 sea ice and the quantity of sea-ice transport through Fram Strait but does not affect the overall
285 results presented in this study (Fig. S2b, c).

286 3.3 Arctic sea-ice thickness and its export to Nordic and Labrador Seas

287 Along the transport path in the direction of Fram Strait, sea ice (mostly driven by dynamical ice
288 growth) increases its thickness between 11 and 20 m (Fig. 4b, c). At this location, temperature and
289 wind stress of the respective model run (LGM1, LGM2) as well as ice resistance, determine the
290 velocity of the ice drift and the sea-ice thickness. As ice drift rates in LGM1 are by up to 2 cm/s
291 lower than in LGM2 (Fig. 5b, c, Fig. S5), the residence time of Arctic sea ice is prolonged, and up
292 to 20 m ice thickness evolves just north of Fram Strait (Fig. 4c). The simulated sea-ice export rate
293 through Fram Strait $((95 \pm 21) \times 10^3 \text{ m}^3/\text{s}$; Table 1) in CTRL is consistent with estimates based on
294 observation values of a 50-yr period (1950–2000: $91.9 \pm 21.1 \times 10^3 \text{ m}^3/\text{s}$; Vinje, 2001). The
295 minimum of present-day sea-ice transport during late summer (Fig. 6) is associated with a dramatic
296 decline in summer ice-drift velocities (Fig. S5). Also present-day sea-ice thickness across Fram
297 Strait decreases in September and recovers during winter months (Fig. S6). Seasonal sea-ice export
298 in CTRL is dominated by changes in ice drift velocities (2.3–10.8 cm/s, Fig. S5). The sea ice melts
299 along the East Greenland Current and rarely reaches the Denmark Strait $((30 \pm 10) \times 10^3 \text{ m}^3/\text{s}$ of sea-

ice export). However up to three times more sea-ice quantity exiting through Fram Strait in the glacial model runs LGMG and LGMC (Table 1) is transported into the Nordic Seas (Fig. 6). The elevated glacial sea-ice flux into the Nordic Seas is caused by thicker sea ice exiting the Fram Strait (Fig. S6). During summer the glacial ice cover destabilizes north of Fram Strait and thick sea ice, up to 10.5 m in LGMC and 8.5 m in LGMG, is crossing the gateway (Fig. S6), causing maximum sea-ice export in September (Fig. 6). During the rest of the year glacial sea-ice export is predominantly influenced by variation of ice drift velocity (Fig. S5). The ice drifts via the East Greenland Current southwards into the ablation areas of the Labrador Sea and into the region south of Iceland (Fig. 5b, c). Here, it becomes apparent that the sea-ice export through the Denmark Strait (LGMG: $(348 \pm 17) \times 10^3 \text{ m}^3/\text{s}$; LGMC: $(163 \pm 30) \times 10^3 \text{ m}^3/\text{s}$; Table 1) reacts to changes in wind fields. Additional sea ice, formed in the Nordic Seas, is transported in LGMG via the Denmark Strait in the direction of the Labrador Sea. This is due to enhanced cyclonic circulation over Iceland (Fig. 2c). In LGMC_PDw and LGMG_PDw, the ocean model is forced with present-day wind fields: Sea-ice export through Fram Strait is significantly reduced (Fig. S3), the gradient of sea-ice thickness (Fig. S4a, b), and local areas of sea-ice formation in the Arctic Ocean change. Without katabatic winds off the Barents-Sea ice sheet and stronger westerlies than during LGM (Fig. 2) the zonal gradient of sea-ice cover is not simulated (Fig. S4a, b). From late summer until late spring (August until March) the southward transport of sea-ice through Faroe-Shetland Passage and across Iceland-Faroe Ridge is reversed (not shown). Therefore the standard deviation, shown in Table 1 exceeds the mean of sea-ice export through both gateways.

4. Discussion

4.1 Model performance under glacial conditions

The ice strength parameter, formulating rheology of sea-ice models, is tuned to fit present-day observational values. It describes the softness/hardness of sea ice relevant for deformation processes and build-up of pressure ridges and is typically adapted to the time step of the atmospheric forcing.

326 The actual ice thickness is directly affected by this parameter and exhibits a linear relationship to
327 ice strength. For sea-ice thicknesses >3m, where sea-ice growth is primarily driven by ridging and
328 rafting, the ice strength might be underestimated (non-linear) leading to anomalous high pressure
329 ridges like shown in the present-day simulation at CAA and northern Greenland (Fig. 4a). The
330 compressive strength of sea ice sheets increases as the ice thickens due to the fact that thick sea ice
331 is generally less saline as shown by material measurements (Timco and Frederking, 1990). But still,
332 material properties of old multiyear sea ice are poorly observed (Timco and Weeks, 2010).
333 Consequently the glacial model simulations would suggest a rather extreme case of sea-ice
334 thickness in the central Arctic Ocean. For elaborating the effect of ice strength parameterization
335 sensitivity studies of varying ice strength parameter values could be setup and a regime shift in case
336 of extreme ice thicknesses might be implemented in the model. Since these problems are beyond the
337 scope of our work, follow-up studies of the glacial Arctic marine cryosphere and tuning of the
338 present-day model configuration can focus on these questions.

339 It should be noted, that our model approach lacks potential atmosphere-ocean feedbacks (Bengtsson
340 et al., 2004; Semenov et al., 2009), especially in the hydrological cycle and Bering Strait through
341 flow by the restoring term (see section 2.1.2). The freshwater budget and surface runoff affecting
342 the stratification in the Arctic Ocean during LGM remains unclear and has to be defined in more
343 detail, since our studies suggest that stratification is dominated by salinity.

344 Jakobsson et al. (2010) test the freshwater balance of a conceptual two-layer model of the Arctic
345 Ocean. A decrease in freshwater supply of the upper Arctic halocline layer (as expected by a
346 decrease in the hydrological cycle of a cold climate, see section 2.1.2) results in an increase of
347 Atlantic water influx through Fram Strait (Jakobsson et al., 2010). However, interpreted
348 neodymium isotope data from the ACEX sediment core location, Lomonosov Ridge, suggest a
349 longer residence time of bottom water masses during glacial intervals (Haley et al., 2008). Here we
350 reconcile glacial water mass exchange through Fram Strait by a three dimensional ocean simulation.
351 The glacial model scenarios show a consistent, stronger than present-day water mass exchange

352 across Fram Strait (Fig. S7). Modifications of the Arctic freshwater balance and thus surface
353 halocline waters do not effectively change the through flow of Fram Strait waters (Fig. S7) favoring
354 inflow of North Atlantic waters as an operator. Experiments testing the prescribed southern
355 boundary barotropic stream function with a glacial model setup have only minor affects on the
356 Arctic Ocean (Fig. S8). However, Kauker et al. (2005) have shown that changes in the baroclinicity
357 of southern boundary characteristics of the model with a present-day setup can progress into the
358 Arctic within two years. Indeed model-data comparison actually favor a shoaling and weakening of
359 the glacial Atlantic Meridional Overturning Circulation (Hesse et al., 2011, and references therein),
360 which suggests stronger baroclinicity in the North Atlantic sector.

361 Earlier experiments with NAOSIM show a strong effect of continental freshwater and Pacific water
362 through Bering Strait on the Arctic circulation (Prange and Lohmann, 2003; Lohmann et al., 2005).
363 For the early Holocene, the model studies suggest that a gradual increase in the flux of Pacific water
364 through Bering Strait slowly affects the polar climate by melting ice, increasing stratification, and
365 causing an enhanced anticyclonic pattern over the Canadian Basin and the East Siberian Sea
366 (Lohmann et al., 2005; Dyck et al., 2010). As a logical next step, we will elaborate the effect of
367 Arctic freshwater on the Arctic circulation during the termination of the LGM.

368 4.2 Atmospheric circulation of the glacial Nordic Seas.

369 Our results are also interesting for the validation of paleoclimate reconstructions. In the Nordic
370 Seas, the prescribed atmospheric boundary conditions are not consistent with the simulated sea-ice
371 cover. Neither a perennial ice cover proposed by CLIMAP (1981) nor a seasonal ice cover
372 (GLAMAP; Pflaumann et al., 2003) is captured by our studies, indicating a general mismatch of
373 ocean/sea-ice dynamics and SST-reconstruction. This emphasizes the importance of ice sheets and
374 SST reconstruction in the Atlantic sector modifying the atmospheric circulation (Byrkjedal et al.,
375 2006) and therefore sea-ice cover.

376 The annual mean sea-ice export from the Arctic (0.19–0.26 Sv) continues south via the EGC and is
377 modified by sea ice melting along the way, being deflected or reinforced by seasonal ice, which

378 mainly evolved in the Norwegian Sea (not shown). Due to zonal drift patterns, a gradient of sea-ice
379 thickness becomes apparent in the Nordic Seas (Fig. 4b,c). Meland et al. (2005) also find the pattern
380 of that gradient in their SST reconstruction. In the absence of katabatic winds off the Barents-Sea
381 ice sheet, the zonal pattern cannot be obtained (Fig. S4). Byrkjedal et al. (2006) have shown that
382 the presence of sea-ice in the northern North Atlantic sector diminishes the Icelandic Low in
383 contrast to less sea ice in the northern North Atlantic Ocean which favors the formation of a
384 cyclonic pattern. In turn LGMG suggests that a moderate cyclonic circulation over Iceland
385 contributes to enhanced sea-ice export across Denmark-Strait. The sea-ice transport from the Arctic
386 Ocean and the Nordic Sea across the Denmark Strait (0.16–0.32 Sv) contributes to the freshwater
387 budget in the northern North Atlantic.

388

389

390 4.3 Hypotheses of the glacial marine cryosphere in the central Arctic Ocean

391 The solid lines shown in Fig. 1 indicate the glacial ice drift proposed by Bischof and Darby (1997),
392 compared to the recent patterns (dashed lines). Present sea-ice formation and sediment entrainment
393 take place primarily in shallow water (<50 m water depth) of the Siberian Shelf. The Laptev Sea
394 and the Kara Sea are important regions for sediment-laden sea ice along today`s Transpolar Drift
395 (Nürnberg et al., 1994). This signal is reflected for the last 8 ka in the fine-grained sediment
396 composition, an indicator for sea-ice rafted debris (Pfirman et al., 1989; Reimnitz et al., 1998;
397 Nürnberg et al., 1994). The provenance of Fram Strait sediment was determined by matching the
398 chemical signature of detrital iron oxide grains to >2000 potential circum-Arctic source
399 compositions (Darby et al., 2002; Darby and Zimmerman, 2008). The sediments of the last ice age
400 in the Fram Strait sediment core PS1230 are primarily from the Canadian Arctic Archipelago
401 (Banks Island, Queen Elizabeth Island), which was covered by the Laurentide and Innuitian ice
402 sheets at that time (Ehlers and Gibbard, 2007). Calving Laurentide ice into the Arctic Ocean at this
403 time occurred along the Amundsen Trough (Stokes et al., 2006) and the M'Clure Strait (Stokes et

404 al., 2005). It has not yet been clarified whether these calving events led to an ice shelf in the Arctic
405 Ocean or whether perennial sea ice with icebergs of Antarctic dimension prevailed (Jakobsson et
406 al., 2010). The Eurasian shelf seas were either covered by the Fennoscandinavian ice sheet (Ehlers
407 and Gibbard, 2007) or exposed.

408 We propose that icebergs, which are also an important transport medium for sediments especially
409 during the transition from glacial maxima to deglacial intervals, moved in the Arctic Ocean
410 synchronously with sea ice. While the iceberg drift is usually directed by several forces (water drag,
411 wind stress, Coriolis force, inclination of the sea surface and interaction with sea-ice cover), iceberg
412 drift buoys in the Weddell Sea (Antarctic) confirm that there is a coherent sea ice/iceberg
413 movement at ~90% sea-ice concentration (Schodlok et al., 2006). Low sedimentation rates, the
414 absence of microorganisms, or even a hiatus in the sediment record, actually imply a thicker than
415 today perennial ice cover with little melting in the central Arctic Ocean (Nørgaard-Pedersen et al.,
416 1998; Polyak et al., 2004; Stein et al., 1994; Stein, 2008). The model studies show a gradient of sea-
417 ice thickness across the Arctic Ocean that is different from today. Due to the convergence of drift,
418 sea ice is compressed to thicknesses of 11–20 m just north of Greenland and the advection area of
419 Fram Strait, comparable to the recent pressure ridges of up to 20–30 m thickness in this area (e.g.,
420 Polyak et al., 2010). Whereas halted sea-ice would accumulate snowfall which slowly converts
421 snow to firn and glacier ice up to 40 m height as seen from landfast-ice remnants of the little ice-age
422 (Bradley and England, 2008). In this case variations of ice thickness in the central Arctic Ocean
423 would be dependent on the surface mass balance and thermodynamic processes. Bradley and
424 England (2008) argue that limited atmospheric circulation in the glacial Arctic Ocean favor this
425 process and propose a mean ice thickness of 50 m in the Arctic Ocean. In the atmospheric forcing
426 of our model studies, the North Pacific westerlies at the Laurentide ice sheet diverge forming a
427 southern and northern branch. Winds of the northern branch are redirected across CAA intruding to
428 the Arctic interior where sea-ice along the coast of CAA is pushed offshore to the central Arctic

429 Ocean. Sea ice is converging and pressure ridges of exceptional height evolve along its way towards
 430 Fram Strait forming a trans-arctic gradient of sea-ice thickness controlled by sea-ice dynamics.

431 4.4 Comparison of simulated and reconstructed glacial ice drift

432 Pleistocene ice drift reconstruction is illustrated by Phillips and Grantz (2001) utilizing the average
 433 MIS2 composition and distribution of erratics in Arctic Ocean sediments. They propose that the
 434 main Arctic circulation patterns, the Beaufort Gyre and Transpolar Drift operated, on average,
 435 during late Pleistocene glacial episodes. Further they associate westward migration of eolian sand
 436 dunes across northern Alaska (e.g. Dinter et al., 1990) with wind patterns driving the Beaufort Gyre
 437 at least since the LGM. In general these findings agree with the applied wind forcing fields of our
 438 model studies (Fig. 2b, c) as well as the anticyclonic sea-ice rotation in the Amerasian Basin (Fig.
 439 5b, c).

440 Furthermore, ice plough marks (Fig. 1, blue arrows) along the Alaskan Beaufort Sea shelf edge and
 441 the border area of the Chukchi Sea, dated to the LGM, imply the orientation of ice drift (Engels et
 442 al., 2008; Polyak et al., 2001; Polyak et al., 2007), which is consistent with the clockwise
 443 circulation in our model studies (Fig. 5b,c). Based on the IRD and DFA analysis Bischof and Darby
 444 (1997) reconstruct iceberg trajectories originating from northwest Canada and the western Canadian
 445 Arctic Archipelago (Amundson Trough) traversing the Northwind Ridge and Chukchi Plateau
 446 before reaching Fram Strait. Icebergs sourcing from the Queen Elizabeth Islands primarily take a
 447 more direct route across central and southeastern Alpha Ridge (Bischof and Darby, 1997). They
 448 state that icebergs from the Innuitian and Laurentide ice-sheet take a direct pathway out of the
 449 Arctic Ocean without multiple anticyclonic rotations in the Amerasian Basin (Fig. 1, blue lines). In
 450 our glacial model studies we still observe a downscaled anticyclonic gyre of ice drift in the Western
 451 Arctic whose center of rotation is shifted towards CAA compared to the present-day. This actually
 452 allows ice of the northern edge of the Laurentide ice-sheet to traverse the central Arctic Ocean in an
 453 arched pattern along the western Arctic shelf margin without multiple rotation in the glacial gyre
 454 (Fig. 5b,c) as proposed by Bischof and Darby (1997). During at least two glacial maxima,

diamicton was deposited by grounding ice at the Chukchi Borderland (Polyak et al., 2007), which would divert sea-ice drift further northwards. Ice at the rim of the Innuitian ice sheet either takes the same arched pattern (LGMG, Fig. 5b) or slowly moves parallel to the coast of northern Greenland towards Fram Strait (LGMC, Fig. 5c). Differences in the atmospheric circulation (Fig. 2c) and pressure fields in the Arctic cause deviations in size and location of the anticyclonic ice drift pattern of LGMC and LGMG (Fig. 5). Further the reduced speed of sea-ice drift of our glacial model studies is directly affected by increased internal ice stress due to elevated ice thickness (not shown). Between Ellesmere Island and North Greenland (Lincoln Sea) Larsen et al. (2010) mapped glacial landforms and sediments and found evidence of shelf-based ice during the early stages of the last glacial ~30ka ago, which is not in the scope of the ocean/sea-ice model. For the formation of an ice shelf, thick multiyear sea-ice is required in order to disable shelf-ice calving into the ocean (Jakobsson et al., 2010; Larsen et al., 2010). The initialization started with outlet glacier streams that were deflected by the eastward sea-ice movement and final coalescence into an ice-shelf (Larsen et al., 2010). In our model studies, the Lincoln Sea is occupied by perennial sea-ice of maximum thickness (Fig. 4b, c) and virtually no ice-drift (Fig. 5b, c), which are favorable conditions for sustaining an ice-shelf. Further north, multi-year ice is drifting at 0.2-1cm/s eastwards in agreement with the scenario of Larsen et al. (2010).

472

473 5. Conclusions

474 The panarctic ice-shelf cover postulated by Grosswald and Hughes (2008) provides an extreme case
475 of glaciation with virtually no ice drift, which is not supported by our model simulations as well as
476 more recent reconstructions (Jakobsson et al., 2010) nor the IRD record in Fram Strait (Darby and
477 Zimmerman, 2008). Phillips and Grantz (2001) point out that the Beaufort Gyre and Transpolar
478 Drift have been stable during late Pleistocene forced by wind fields consistent with proxy evidence
479 from North Alaska. In contrast, our model studies still show an anti-cyclonic rotation in the
480 Canadian Basin, which is shifted compared to the present-day pattern and a Transpolar Drift which

481 is deflected or not present during LGM. Applying modern wind fields to the glacial model setup
482 result in a general mismatch of simulated ice drift, ice cover and proxy data. As a consequence
483 glacial wind stress is interpreted as the dominant operator of sea-ice drift. The arched pattern of
484 simulated sea-ice drift results in a gradient of sea-ice thickness in the Arctic Ocean that is
485 predominantly forced by glacial wind fields. The sources of MIS2 IRD in Fram Strait and other
486 parts of the Arctic (Darby et al., 2002; Darby and Zimmerman, 2008) and the orientation of dated
487 ice plough marks (Engels et al., 2008; Polyak et al., 2001; Polyak et al., 2007) substantiate our
488 results.

489 Our approach overcomes the drawbacks of global climate models in representing circulation
490 changes on a regional scale. The validation of our high-resolution regional Arctic ocean-sea ice
491 model, which has been used for hindcast and sea-ice prediction so far (Kauker et al., 2009) against
492 the Last Glacial Maximum is crucial to understand physical processes concerning other climate
493 regimes than today.

494

495 Acknowledgments

496 We thank the AWI sea ice group for model support and Axel Wagner for technical assistance. Part
497 of the work was funded by the German Science Foundation (DFG) within the research unit UCCC
498 and the Alfred Wegener Institute through the program PACES in collaboration with the
499 Biodiversity and Climate Research Centre BiK-F established in the LOEWE framework. Part of this
500 paper is based on a diploma thesis conducted at the Alfred Wegener Institute in cooperation with
501 Technische Universität Bergakademie Freiberg.

Figure Captions

Fig. 1: Reconstruction of last glacial/interglacial ice drift in the Arctic Ocean. Black land/sea-mask marks the modern and grey, the glacial boundaries of the model. Weighted proportion (wt%) of the iron oxide grains from core PS1230 (Lat 78°51'N, Long 04°46'W; 1,235 m water depth) (Darby et al., 2002; Darby and Zimmerman, 2008), assigned to the individual regions of origin (blue and red areas). Solid blue lines indicate glacial, dashed red lines are interglacial ice drift (Bischof and Darby, 1997). Blue arrows indicate ice plough marks, dated to the LGM (Engels et al., 2008; Polyak et al., 2001; Polyak et al., 2007).

Fig. 2: Atmospheric boundary forcing of wind fields 10 m above surface (m/s) for the respective model studies. (a): 30-year mean (years 1977–2007) of wind fields derived from NCAR/NCEP reanalysis data (Kalnay et al., 1996) to force present-day model run (CTRL). (b): 15-year mean of wind field data referring to the cold glacial experiment LGMC. (c): Anomaly plot of 15-year mean of wind field forcing data LGMG-LGMC.

Fig. 3: Mean sea-ice concentration (100%) for summer (August) in the upper row and winter (February) conditions in the lower row are displayed. (a), (d): Present-day control run CTRL. (b), (e): LGMG. (c), (f): LGMC.

Fig. 4: Mean sea-ice thickness (m) for modern and glacial conditions. (a): Present-day control run (CTRL). (b): LGMG. (c): LGMC.

Fig. 5: Streamlines of 30-yr mean sea-ice drift (cm/s) for modern and glacial conditions. (a): Model study CTRL. (b): LGMG. (c): LGMC. Not shown: sea ice drift with a mean sea ice concentration of

<10% (in general northern North Atlantic; see Fig. 3) and a velocity of <0.2 cm/s (e.g. Canadian Archipelago, Baffin Bay).

Fig. 6: Seasonal cycle of mean sea-ice export ($S_v = 10^6 \text{m}^3/\text{s}$) across the Fram Strait for CTRL, LGMG and LGMC.

Table 1: Mean sea-ice transport and standard deviation ($10^3 \text{m}^3/\text{s}$) through ocean gates of the North Polar Seas and budget of the Nordic Seas are shown for each model study. Positive (negative) values denote sea-ice import (export) to Nordic Seas.

	Fram Strait	Denmark Strait	Iceland-Faroe Ridge	Faroe-Shetland Passage	Δ Nordic Seas sea-ice transport
CTRL	95 ± 21	-30 ± 10	0	0	65
LGMG	264 ± 32	-348 ± 17	-60 ± 14	-3 ± 2	-147
LGMC	194 ± 40	-163 ± 30	-139 ± 26	-8 ± 9	-116
LGMG_PDw	115 ± 38	-153 ± 41	-1 ± 25	6 ± 6	-33
LGMC_PDw	88 ± 33	-146 ± 39	-1 ± 51	27 ± 36	-32
